## 1 Introduction

The concept of first order *moment tensor* provides a complete description of equivalent body forces of a general seismic point source (see Figure 1). A source can be considered a point source if both the distance  $D$  of the observer from the source and the wavelength  $\lambda$  of the data are much greater than the linear dimension of the source. Thus, moment-tensor solutions are generally derived from low-frequency data and they are representative of the gross properties of the rupture process averaged over tens of seconds or more. The double-couple source model describes the special case of shear dislocation along a planar fault. This model has proven to be very effective in explaining the amplitude and polarity pattern of P, S and surface waves radiated by tectonic earthquakes. In the following, we briefly outline the relevant relations (in a first order approximation) between the moment tensor of a seismic source and the observed seismogram. The latter may be either the complete seismogram, one of its main groups (P, S or surface waves), or specific features of seismograms such as peak-to-peak amplitudes of body waves, amplitude ratios or spectral amplitudes. Then we outline a linear inversion scheme for obtaining the moment tensor using waveform data in the time domain. Finally, we will give an overview of some useful programs for moment-tensor analysis. Applications of moment-tensor inversions to the rapid (i.e., generally within 24 hours after the event) determination of source parameters after significant earthquakes will also be described.

## 2 Basic relations

Following Jost and Herrmann (1989), the displacement  $d$  on the Earth's surface at a station can be expressed, in case of a point source, as a linear combination of time-dependent moment-tensor elements  $M_{kj}(\xi, t)$  that are assumed to have the same time dependence convolved (indicated by the star symbol) with the derivative  $G_{skj}(\mathbf{x}, \xi, t)$  of the Green's functions with regard to the spatial  $j$ -coordinate:

$$u_s(\mathbf{x}, t) = M_{kj}(\xi, t) * G_{skj}(\mathbf{x}, \xi, t). \quad (1)$$

$u_s(\mathbf{x}, t)$ :  $s$  component of ground displacement at position  $\mathbf{x}$  and time  $t$

$M_{kj}(\xi, t)$ : components of 2nd order, symmetrical seismic moment tensor  $M$

$G_{skj}(\mathbf{x}, \xi, t)$ : derivative of the Green's function with regard to source coordinate  $\xi_j$

$\mathbf{x}$ : position vector of station with coordinates  $x_1, x_2, x_3$  for north, east and down

$\xi$ : position vector of point source with coordinates  $\xi_1, \xi_2, \xi_3$  for north, east and down

Eq. (1) follows from the representation theorem in terms of the Green's function (see Equations (21) and (38) in IS 3.1). The Green's function represents the impulse response of the medium between source and receiver and thus contains the various wave propagation effects through the medium from source to receiver. These include energy losses through reflection and transmission at seismic discontinuities, anelastic absorption and geometrical spreading. The  $M_{kj}(\xi, t)$  from Eq.(1) completely describes the forces acting in the source and their time dependence. The Einstein summation notation is applied in Eq. (1) and below, i.e., the repeated indices  $k$  and  $j = 1, 2, 3$  imply summation over  $x_1, x_2$  and  $x_3$ . In Eq. (1) the higher order terms of the Taylor expansion around the source point of the Green's functions  $G_{skj}(\mathbf{x}, \xi, t)$  have been neglected. Note that the source-time history  $s(t)$  (see 3.1, Figs. 3.4 and 3.9), which describes the time dependence of moment released at the source, is contained in  $c$ . If we assume that all the components of  $M_{kj}(\xi, t)$  have the same time dependence  $s(t)$  the equation can be written as:

$$u_s(\mathbf{x}, t) = M_{kj} [G_{skj}(\mathbf{x}, \xi, t) * s(t)] \quad (2)$$

with  $s(t)$ : source time history.

When determining  $M_{kj}(\xi, t)$  from seismic records,  $u_s(\mathbf{x}, t)$  is calculated by convolution of the observed seismogram components  $y_s(\mathbf{x}, t)$  with the inverse of the seismograph's displacement response function  $i(t)$ :

$$u_s(\mathbf{x}, t) = y_s(\mathbf{x}, t) * \text{Inv}\{i(t)\}$$

In the frequency domain (see Eq. (14) in IS 3.1) convolution is replaced by multiplication:

$$D_s(\mathbf{x}, \omega) = Y_s(\mathbf{x}, \omega) I(\omega)^{-1}$$

where  $\omega$  is circular frequency. The  $D_s(\mathbf{x}, \omega)$ ,  $Y_s(\mathbf{x}, \omega)$ , and  $I(\omega)^{-1}$  are the respective Fourier transforms of the time series  $d_s(\mathbf{x}, t)$ ,  $y_s(\mathbf{x}, t)$ , and  $i(t)^{-1}$  (see 5.2.7 where  $I(\omega)^{-1}$  is denoted as  $H_d(\omega)^{-1}$ ).

**Figure 1** The nine generalized couples representing  $G_{skj}(\mathbf{x}, \boldsymbol{\xi}, t)$  in Eq. (3.69). Note that force couples acting on the  $y$  axis in  $x$  direction or vice versa (i.e.,  $(x,y)$  or  $(y,x)$ ) will cause shear faulting in the  $x$  and  $y$  direction, respectively. Superimposition of vector dipoles in  $x$  and  $y$  direction with opposite sign, e.g.,  $(x,x) + (-y,-y)$  will also cause shear faulting but  $45^\circ$  off the  $x$  and  $y$  direction, respectively. Both representations are equivalent (reproduced from Jost and Herrmann, A student's guide to and review of moment tensors. *Seismol. Res. Lett.*, **60**, 2, 1989, Fig. 2, p. 39; ©Seismological Society of America).

In the following we assume that the source-time function  $s(t)$  is a delta function (i.e., a "needle" impulse). Then,  $M_{kj}(\boldsymbol{\xi}, t) = M_{kj}(\boldsymbol{\xi}) \cdot \delta(t)$ , and the right side of Eq.(2) simplifies to  $M_{kj}(\boldsymbol{\xi}) \cdot G_{skj}(t)$ . The seismogram recorded at  $\mathbf{x}$  can be regarded as product of  $G_{skj}$  and  $M_{kj}$ . (e.g., Aki and Richards, 1980 and 2002; Lay and Wallace, 1995; Udias, 1999). Thus, the derivative of  $G_{skj}$  with regard to the source coordinate  $\xi_i$  describes the response to a single couple with its lever arm pointing in the  $\xi_j$  direction (see Figure 1). For  $k = j$  we obtain a vector dipole; these are the couples  $(x,x)$ ,  $(y,y)$ , and  $(z,z)$  in Figure 1. A double-couple source is characterized by a moment tensor where one eigenvalue of the moment tensor vanishes (equivalent to the Null or B axis), and the sum of eigenvalues vanishes, i.e., the trace of the moment tensor is zero. Physically, this is a representation of a shear dislocation source without any volume changes.

Using the notation of Figure 1, double-couple displacement fields are represented by the sum of two couples such as  $(x,y) + (y,x)$ ,  $(x,x) + (y,y)$ ,  $(y,y) + (z,z)$ ,  $(y,z) + (z,y)$  etc. An explosion

source (corresponding to  $M_6$  in Eq. (8) and Figure 2) can be modelled by the sum of three vector dipoles  $(x,x) + (y,y) + (z,z)$ . A compensated linear vector dipole (CLVD, see section 4 below) can be represented by a vector dipole of strength 2 and two vector dipoles of unit strength but opposite sign in the two orthogonal directions.

The seismic moment tensor  $\mathbf{M}$  has, in general, six independent components which follows from the condition that the total angular momentum for the equivalent forces in the source must vanish. For vanishing trace, i.e., without volume change, we have five independent components that describe the deviatoric moment tensor. The double-couple source is a special case of the deviatoric moment tensor with the constraint that the determinant of  $\mathbf{M}$  is zero, i.e., that the stress field is two-dimensional.

In general,  $\mathbf{M}$  can be decomposed into an isotropic and a deviatoric part:

$$\mathbf{M} = \mathbf{M}^{\text{isotropic}} + \mathbf{M}^{\text{deviatoric}} \quad (3)$$

The decomposition of  $\mathbf{M}$  is unique while further decomposition of  $\mathbf{M}^{\text{deviatoric}}$  is not. Commonly,  $\mathbf{M}^{\text{deviatoric}}$  is decomposed into a double couple and CLVD:

$$\mathbf{M}^{\text{deviatoric}} = \mathbf{M}^{\text{DC}} + \mathbf{M}^{\text{CLVD}} \quad (4)$$

For a double-couple source, the Cartesian components of the moment tensor can be expressed in terms of strike  $\phi$ , dip  $\delta$  and rake  $\lambda$  of the shear dislocation source (fault plane), and the scalar seismic moment  $M_0$  (Aki and Richards, 1980):

$$\begin{aligned} M_{xx} &= -M_0(\sin\delta \cos\lambda \sin 2\phi + \sin 2\delta \sin\lambda \sin^2\phi) \\ M_{xy} &= M_0(\sin\delta \cos\lambda \cos 2\phi + 0.5 \sin 2\delta \sin\lambda \sin 2\phi) \\ M_{xz} &= -M_0(\cos\delta \cos\lambda \cos\phi + \cos 2\delta \sin\lambda \sin\phi) \\ M_{yy} &= M_0(\sin\delta \cos\lambda \sin 2\phi - \sin 2\delta \sin\lambda \cos^2\phi) \\ M_{yz} &= -M_0(\cos\delta \cos\lambda \sin\phi - \cos 2\delta \sin\lambda \cos\phi) \\ M_{zz} &= M_0 \sin 2\delta \sin\lambda \end{aligned} \quad (5)$$

As the tensor is always symmetric it can be rotated into a principal axis system such that all non-diagonal elements vanish and only the diagonal elements are non-zero. The diagonal elements are the *eigenvalues* (see Eq. (6) in Information Sheet 3.1) of  $\mathbf{M}$ ; the associated directions are the *eigenvectors* (i.e., the *principal axes*). A linear combination of the principal moment-tensor elements completely describes the radiation from a seismic source. In the case of a double-couple source, for example, the diagonal elements of  $\mathbf{M}$  in the principal axis system have two non-zero eigenvalues  $M_0$  and  $-M_0$  (with  $M_0$  the scalar seismic moment) whose eigenvectors give the direction at the source of the tensional (positive) T axis and compressional (negative) P axis, respectively, while the zero eigenvalue is in the direction of the B (or Null) axis of the double couple (for definition and determination of  $M_0$  see Exercise 3.4).

Eq. (2) describes the relation between seismic displacement and moment tensor in the time domain. If the source-time function is not known or the assumption of time-independent

moment-tensor elements is dropped, e.g., for reasons of source complexity, the frequency-domain approach is chosen:

$$u_s(x, f) = M_{kj}(f)G_{skj}(x, \xi, f) \quad (6)$$

where  $f$  denotes frequency. Procedures for the linear moment-tensor inversion can be designed in both the time and frequency domain using Eq. (2) or (6). We can write (2) or (6) in matrix form:

$$\mathbf{u} = \mathbf{G} \bar{\mathbf{m}}. \quad (7)$$

In the time domain, the  $\mathbf{u}$  is a vector containing  $n$  sampled values of observed ground displacement at various times, stations and sensor components, while  $\mathbf{G}$  is a  $6 \times n$  matrix and the vector  $\bar{\mathbf{m}}$  contains the six independent moment-tensor elements to be determined. In the frequency domain,  $\mathbf{u}$  contains  $k$  complex values of the displacement spectra determined for a given frequency  $f$  at various stations and sensor components.  $\mathbf{G}$  is a  $6 \times k$  matrix and is generally complex like  $\bar{\mathbf{m}}$ . For more details on the inversion problem in Eq. (7) the reader is referred to Chapter 6 in Lay and Wallace (1995), Chapter 12 in Aki and Richards (1980), or Chapter 19 of Udias (1999).

To invert Eq. (7) for the unknown  $\bar{\mathbf{m}}$ , one has to calculate the derivatives of the Green's functions. The calculation of the Green's functions constitutes the most important part of any moment-tensor inversion scheme. A variety of methods exists to calculate synthetic seismograms (e.g., Müller, 1985; Doornbos, 1988; Kennett, 1988). Some of the synthetic seismogram codes allow calculations for the moment-tensor elements as input source while others allow input for double-couple and explosive point sources. The general moment tensor can be decomposed in various ways using moment-tensor elements of double-couple and explosive sources so that synthetic seismogram codes employing these source parameterizations can also be used in the inversion of (7).

### 3 An inversion scheme in the time domain

In this section, we will describe in short the moment-tensor inversion algorithm of Kikuchi and Kanamori(1991), where the moment tensor is decomposed into elementary double-couple sources and an explosive source. Adopting the notation used by Kikuchi and Kanamori(1991), the moment tensor  $M_{kj}$  is represented by a linear combination of  $N_e = 6$  elementary moment tensors  $M_n$  (Figure 2):

$$M_{kj} = \sum_{n=1}^{N_e} a_n M_n \quad (8)$$

with

$$M_1 : \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}; \quad M_2 : \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{bmatrix}; \quad M_3 : \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}$$

$$M_4: \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix}; M_5: \begin{bmatrix} -1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}; M_6: \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

The  $M_1$  and  $M_2$  represent pure strike-slip faults;  $M_3$  and  $M_4$  represent dip-slip faults on vertical planes striking N-S and E-W, respectively, and  $M_5$  represents a 45° dip-slip fault. The  $M_6$  represents an isotropic source radiating energy equally into all directions (i.e., an explosion).

## Elementary Moment Tensors

**Figure 2** Elementary moment tensors used in the inversion of the full moment tensor (after Kikuchi and Kanamori, 1991)

A pure deviatoric moment tensor ( $\text{trace}(M_{kj}) = 0$ ) is entirely represented by the five elementary moment tensors  $M_1$  to  $M_5$ . The following brief description of the linear inversion for the moment tensor (Kikuchi and Kanamori, 1991) is an example of an inversion performed in the time domain. It can be easily adopted for an inversion in the frequency domain by replacing the time series by their spectra. Let  $w_{sn}(t)$  denote the Green's function derivative at station  $s$  in response to the elementary moment *tensor*  $M_n$ , and let  $x_s(t)$  be the observed ground displacement as function of time at station  $s$ . The best estimate for the coefficients  $a_n$  in Eq. (8) can be obtained from the condition that the difference between observed and synthetic displacement functions be zero:

$$\begin{aligned} \Delta &= \sum_{s=1}^{N_s} \int \left[ x_s(t) - \sum_{n=1}^{N_e} a_n w_{sn}(t) \right]^2 dt \\ &= R_x - 2 \sum_{n=1}^{N_e} a_n G_n + \sum_{m=1}^{N_e} \sum_{n=1}^{N_e} R_{nm} a_n a_m \\ &= \text{Minimum} \end{aligned} \tag{9}$$

The  $N_e$  is the number of elementary moment tensors, and  $N_s$  is the number of displacement records used. The other terms in (9) are given by:

$$R_x = \sum_{s=1}^{N_s} \int [x_s(t)]^2 dt$$

$$R_{nm} = \sum_{s=1}^{N_s} \int [w_{sn}(t) w_{sm}(t)] dt$$

$$G_n = \sum_{s=1}^{N_s} \int [w_{sn}(t) x_s(t)] dt$$

Integration is carried out over selected portions of the waveforms. Evaluating  $\partial\Delta/\partial a_n = 0$  for  $n = 1, \dots, N_e$  yields the normal equations

$$\sum_{m=1}^{N_e} R_{nm} a_m = G_n \quad (10)$$

with  $n$  ranging from 1 to  $N_e$ . The solution for  $a_n$  is given by:

$$a_n = \sum_{m=1}^{N_e} R_{nm}^{-1} G_m \quad (11)$$

The inverse  $R_{nm}^{-1}$  of matrix  $R_{nm}$  can be obtained by the method of generalized least squares inversion (e.g., Pavlis, 1988). The resultant moment tensor is then given by

$$M_{kj} = \begin{bmatrix} a_2 - a_5 + a_6 & a_1 & a_4 \\ a_1 & -a_2 + a_6 & a_3 \\ a_4 & a_3 & a_5 + a_6 \end{bmatrix} \quad (12)$$

The variance of the elements  $a_n$  can be calculated under the assumption that the data are statistically independent:

$$\text{var}(a_n) = \sum_{m=1}^{N_e} (R_{nm}^{-1})^2 \sigma_m^2$$

where  $\sigma_m^2$  is the variance of the data  $G_n$ . In the case where the variance of the data is not known,  $\sum_{m=1}^{N_e} (R_{nm}^{-1})^2$  can be used as relative measure for the uncertainty.

#### 4 Decomposition of the moment tensor

Except for the volumetric and deviatoric components, the decomposition of the moment tensor is not unique. Useful computer programs for decomposition were written by Jost and distributed in Volume VIII of the Computer Programs in Seismology by Herrmann of Saint Louis University (<http://www.eas.slu.edu/People/RBHerrmann/ComputerPrograms.html>) or e-mail to R. W. Herrmann: [rbh@slueas.slu.edu](mailto:rbh@slueas.slu.edu)). The first step in the decomposition is the calculation of eigenvalues and eigenvectors of the seismic moment tensor. For this the

program *mteig* can be used. It performs rotation of the moment tensor  $\mathbf{M}$  into the principal axis system. The eigenvector of the largest eigenvalue gives the T (or tensional) axis; the eigenvector of the smallest eigenvalue gives the direction of the P (or compressional) axis, while the eigenvector associated with the intermediate eigenvalue gives the direction of the Null axis. The output of *mteig* is the diagonalized moment tensor

$$M = \begin{bmatrix} m_1 & 0 & 0 \\ 0 & m_2 & 0 \\ 0 & 0 & m_3 \end{bmatrix} \quad (13)$$

whose elements are input to another program, *mtdec*, which performs a moment-tensor decomposition. First, the moment tensor is decomposed into an isotropic and a deviatoric part (see Eq. 3):

$$M = \frac{1}{3} \begin{bmatrix} tr(M) & 0 & 0 \\ 0 & tr(M) & 0 \\ 0 & 0 & tr(M) \end{bmatrix} + \begin{bmatrix} m_1^1 & 0 & 0 \\ 0 & m_2^1 & 0 \\ 0 & 0 & m_3^1 \end{bmatrix} \quad (14)$$

with  $tr(\mathbf{M}) = m_1 + m_2 + m_3$  being the trace of  $\mathbf{M}$ . The isotropic part of  $\mathbf{M}$  is important in quantifying volume changes of the source, but it is usually difficult to resolve so that isotropic parts of less than 10% are often not considered to be significant. The deviatoric part of the moment tensor can be further decomposed. Options include decompositions into three vector dipoles, into three double couples, into 3 CLVD sources, into a major and minor double couple, and into a best double couple and a CLVD having the same principal axis system. The source mechanisms reported by Harvard and USGS are based on the decomposition of the moment tensor into a best double couple and a CLVD. In addition to the best double couple they also provide the moment-tensor elements. To estimate the double-couple contribution to the deviatoric moment tensor, the parameter

$$\varepsilon = \frac{|m_{\min}|}{|m_{\max}|}$$

is used (Dziewonski et al., 1981) where  $m_{\min}$  and  $m_{\max}$  are the smallest and largest eigenvalues of the deviatoric part of  $\mathbf{M}$ , respectively, both in absolute terms. For a pure double-couple source,  $\varepsilon = 0$  because  $m_{\min} = 0$ ; for a pure CLVD,  $\varepsilon = 0.5$ . The percentage double-couple contribution can be expressed as  $(1-2\varepsilon) \times 100$ . Significant CLVD components are often reported for large intermediate-depth and very deep earthquakes. In many cases, however, it can be shown that these are caused by superposition of several rupture events with different double-couple mechanisms (Kuge and Kawakatsu, 1990; Frohlich, 1995; Tibi et al., 1999).

Harvard and USGS publish the moment tensors using the notation of normal mode theory. It is based on spherical co-ordinates  $(r; \Theta; \Phi)$  where  $r$  is the radial distance of the source from the

center of the Earth,  $\Theta$  is co-latitude, and  $\Phi$  is longitude of the point source. The 6 independent moment-tensor elements in the  $(x, y, z) = (\text{north, east, down})$  coordinate system are related to the components in  $(r; \Theta; \Phi)$  by

$$M_{rr} = M_{zz}$$

$$M_{\Theta\Theta} = M_{xx}$$

$$M_{\Phi\Phi} = M_{yy}$$

$$M_{r\Theta} = M_{zx}$$

$$M_{r\Phi} = -M_{zy}$$

$$M_{\Theta\Phi} = -M_{xy}$$

## 5 Steps taken in moment-tensor inversion

Generally, the quality of moment-tensor inversion depends to a large extent on the number of data available and the azimuthal distribution of stations about the source. Dufumier (1996) gives a systematic overview for the effects caused by differences in the azimuthal coverage and the effects caused due to the use of only P waves, P plus SH waves or P and SH and SV waves for the inversion with body waves.

A systematic overview with respect to the effects caused by an erroneous velocity model for the Green function calculation and the effects due to wrong hypocenter coordinates can be found in Šílený et al. (1992), Šílený and Pšenčík (1995), Šílený et al. (1996) and Kravanja et al. (1999).

The following is a general outline of the various steps to be taken in a moment-tensor inversion using waveform data:

### 1) Data acquisition and pre-processing

- good signal-to-noise ratio
- unclipped signals
- good azimuthal coverage
- removing mean value and linear trends
- correcting for instrument response, converting seismograms to displacement
- low-pass filtering to remove high-frequency noise and to satisfy the point source approximation

### 2) Calculation of synthetic Green's functions dependent on

- Earth model
- location of the source
- receiver position

### 3) Inversion

- selection of waveforms, e.g., P, S H or full seismograms
- taking care to match waveforms with corresponding synthetics
- evaluation of Eqs. (8) and (9)
- decomposition of moment tensor, e.g., into best double couple plus CLVD

The inversion may be done in the time domain or frequency domain. Care must be taken to match the synthetic and observed seismograms. Alignment of observed and synthetic waveforms is facilitated by cross-correlation techniques. In most moment-tensor inversion schemes, focal depth is assumed to be constant. The inversion is done for a range of focal depths and as best solution one takes that with the minimum variance of the estimate.

## 6 Some methods of moment-tensor inversion

### 6.1 NEIC fast moment tensors

This is an effort by the U.S. National Earthquake Information Center (NEIC) in co-operation with the IRIS Data Management Center to produce rapid estimates of the seismic moment tensor for earthquakes with body-wave magnitudes  $\geq 5.8$ . Digital waveform data are quickly retrieved from “open” IRIS stations and transmitted to NEIC by Internet. These data contain teleseismic P waveforms that are used to compute a seismic moment tensor using a technique based on optimal filter design (Sipkin, 1982). Near real-time Current Fast Moment Tensor Solutions are available via <http://earthquake.usgs.gov/earthquakes/eqarchives/fm/>. One can also subscribe via <https://ssleearthquake.usgs.gov/ens/> to a free Earthquake Notification Service (ENS) that sends automated notification E-mails when earthquakes happen in the area of interest to the subscriber

### 6.2 Harvard and Lamont CMT solutions

The Harvard group developed and maintained an extensive catalog of centroid moment-tensor (CMT) solutions for strong (mainly  $M > 5.5$ ) earthquakes over the period from 1976-2006. Since then it is maintained and continued by the Global Centroid Moment Tensor Project (GCMT) at the Lamont-Doherty Earth Observatory (LDEO) of Columbia University. The main dissemination point for information and results from this project (e.g., description of the CMT procedure, global CMT Catalog Search, CMT catalog and quick CMT ACII files, special studies of particular earthquakes or sets of earthquakes) is now via the website <http://www.globalcmt.org>. The Harvard CMT method makes use of both very long-period ( $T > 40$  s) body waves (from the P wave onset until the onset of the fundamental modes) and so-called mantle waves at  $T > 135$  s that comprise the complete surface-wave train. Starting with earthquakes in 2004, the GCMT analysis includes now also intermediate-period surface waves in the moment-tensor inversion. This allows the globally uniform determination of moment tensors for earthquakes down to  $M_w = 5.0$  (Ekström et al., 2012).

Besides the moment tensor the iterative inversion procedure seeks a solution for the best point source location of the earthquake. This is the point where the system of couples is located in the source model described by the moment tensor. It represents the integral of the moment density over the extended rupture area. This centroid location may, for very large earthquakes, significantly differ from the hypocenter location based on arrival times of the first P-wave onsets. The hypocenter location corresponds to the place where rupture started. Therefore, the

offset of the centroid location relative to the hypocentral location gives a first indication on fault extent and rupture directivity. In case of the August 17, 1999 Izmit (Turkey) earthquake the centroid was located about 50 km east of the "P-wave" hypocenter. The centroid location coincided with the area where the maximum surface ruptures were observed.

### 6.3 EMSC and GFZ rapid source parameter determinations

This is an initiative of the European-Mediterranean Seismological Center (Bruyeres-le-Chatel, France, <http://www.emsc-csem.org/>) and the GEOFON Programs at the GeoForschungs-Zentrum Potsdam (<http://www.gfz-potsdam.de/geofon/>). The EMSC method uses a grid search algorithm to derive the fault-plane solutions and seismic moments of earthquakes ( $M > 5.5$ ) in the European-Mediterranean area. Solutions are derived within 24 hours after the occurrence of the event. The data used are P- and S-wave amplitudes and polarities. Figure 3 shows one of the early examples of the kind of output data produced. Nowadays near real-time CMT solutions also for earthquakes world-wide can be obtained via <http://geofon.gfz-potsdam.de/eqinfo/> and one may also **subscribe** receiving automatic earthquake notification e-mails by filling-in the Alert Mailing List Registration form of the GEOFON Rapid Earthquake Information Service (see link via <http://www.gfz-potsdam.de/geofon/>).

### 6.4 Relative moment-tensor inversion

Especially for the inversion of local events so called relative moment-tensor inversion schemes have been developed (Oncescu, 1986; Dahm, 1996). If the sources are separated by not more than a wavelength, the Green's functions can be assumed to be equal with negligible error. In this case it is easy to construct a linear equation system that relates the moment-tensor components of a reference event to those of another nearby event. This avoids the calculation of high-frequency Green's functions necessary for small local events and all problems connected with that (especially the necessity of modeling site transfer functions in detail).

This is a very useful scheme for the analysis of aftershocks if a well determined moment tensor of the main shock is known. Moreover, if enough events with at least slightly different mechanisms and enough recordings are available, it is also possible to eliminate the reference mechanism from the equations (Dahm, 1996). This is interesting for volcanic areas where events are swarm-like and of similar magnitude, and where a reference moment tensor can not be provided (Dahm and Brandsdottir, 1997).

### 6.5 NEIC broadband depths and fault-plane solutions

Moment-tensor solutions, which are generally derived from low-frequency data, reflect the gross properties of the rupture process averaged over tens of seconds or more. These solutions may differ from solutions derived from high frequency data, which are more sensitive to the dynamic part of the rupture process during which most of the seismic energy is radiated. For this reason, beginning January 1996, the NEIC has determined, whenever possible, a fault plane solution and depth from broadband body waves for any earthquake having a magnitude greater than about 5.8 and it has published the source parameters in the Monthly Listings of

the PDE. The broadband waveforms that are used have a flat displacement response over the frequency range 0.01-5.0 Hz. (This bandwidth, incidentally, is also commensurate with that used by the NEIC to compute teleseismic  $E_s$ .) Initial constraints on focal mechanism are provided by polarities from P, pP and PKP waves, as well as by Hilbert-transformed body waves of certain secondary arrivals (e.g., PP), and from transversely polarized S waves. The fault-plane solution and depth are then refined by least-squares fitting of synthetic waveforms to teleseismically recorded P-wave groups (consisting of direct P, pP and sP). More information can be found under [http://neic.usgs.gov/neis/nrg/bb\\_processing.html](http://neic.usgs.gov/neis/nrg/bb_processing.html).

|                                                                                                                                                                                               |              |                |                |                 |                                                                                                                                                                                                       |  |  |  |  |

## 1 Introduction

The following brief guide to moment tensor inversion discusses the characteristics of moment tensors, its physical interpretation and the different ways to decompose moment tensors. It reviews the basic equations used in different inversion schemes, clarifies the role of Green's

functions, and summarizes different practical aspects of moment tensor inversions for different types of waves and different distance ranges (local, regional and global earthquakes). Typical resolution problems of moment tensor components are discussed. The IS provides some guidelines to start moment tensor studies, and thereby introduces a modern, python based moment tensor toolbox (Kiwi Tools) that is flexible to adapt to all specific source studies and incorporates pre-calculated Green's function databases. The complementing exercise EX 3.6 provides a practical on moment tensor inversion using the Kiwi Tools. The IS does not derive the fundamental concepts and the theory of source representations, since this is given in chapter 3 and IS3.1 of the NMSOP-2.

The material is based in large parts on a review paper by Jost and Herrmann (1989) and on lecture notes and practicals we developed during several training courses on moment tensors between 2000 and 2012 (e.g. ESC and IUGG training courses, ICTP workshops in Trieste, Winterschool Sudelfeld). The material updates and extends IS3.8 in NMSOP by Günther Bock on moment tensor determination and decomposition.

### 1.1 Nomenclature and terms

The following nomenclature is used (unit in parentheses):

**Table 1:** Nomenclature

| Parameter                                       | Explanation                                                        | Type                                                      |
|-------------------------------------------------|--------------------------------------------------------------------|-----------------------------------------------------------|
| $t$ and $\tau$                                  | Time, referenced to receiver and source, respectively              | Scalars (s)                                               |
| $\omega$                                        | Angular frequency                                                  | Scalar (rad)                                              |
| $\mathbf{x}$ and $\xi$                          | Spatial coordinates of source and receivers                        | Vectors (m)                                               |
| $\mathbf{M}$ and $\mathbf{m}$                   | Moment tensor and moment tensor density                            | 2 <sup>nd</sup> rank tensors, (Nm and Nm/m <sup>2</sup> ) |
| $\mathbf{G}$                                    | Green's tensor                                                     | 3 <sup>rd</sup> rank tensor (m)                           |
| $\mathbf{u}$ and $\mathbf{D}$                   | Displacement and dislocation across fault                          | Vectors (m)                                               |
| $\mathbf{c}$                                    | Elasticity tensor                                                  | 4 <sup>th</sup> rank tensor (Pa)                          |
| $A$ and $V$                                     | Surface and volume of source                                       | Scalars (m <sup>2</sup> and m <sup>3</sup> )              |
| $\phi, \varphi, \lambda, \delta, \alpha, \beta$ | Angles                                                             | Scalars (rad)                                             |
| $\delta, \delta$ or $\delta_{ij}$               | Kronecker symbol, see e.g. IS3.1                                   | Scalar or 2 <sup>nd</sup> rank tensor                     |
| $N, \eta, K$                                    | 1 <sup>st</sup> and 2 <sup>nd</sup> Lamé's constant and bulk modul | Scalars (Pa)                                              |
| $\mathbf{F}$ and $\mathbf{f}$                   | Point force and force density                                      | Vector (N or N/m <sup>3</sup> )                           |
| $r$                                             | Distance                                                           | Scalar (m)                                                |
| $\gamma$                                        | Direction cosine                                                   | Vector (rad)                                              |
| $\mathbf{n}, \mathbf{l}$                        | Unit vectors (e.g. fault normal or slip direction)                 |                                                           |
| $\mathbf{s}$                                    | Slowness vector                                                    | Vector (s/m)                                              |
| $\mathbf{e}$                                    | Eigenvalue vector of moment tensor                                 | Vector (Nm)                                               |
| $h(t)$                                          | Source time function of the point source                           | Dimensionless                                             |

We use bold face letters (e.g.  $\mathbf{x}$ ) to express vectors and tensors. Scalars are denoted in normal (not bold face) letters. Components of vectors and tensors are denoted by  $x_i$  and  $M_{ij}$ , respectively, where indices usually vary between 1, 2, and 3. We further apply the Einstein summation convention, meaning that repeating indices in one term imply summation over the index, i.e.  $e_k n_k = \sum e_k n_k = e_1 n_1 + e_2 n_2 + e_3 n_3$ . Indices separated by comma “,” denote partial

derivatives to space coordinates, i.e.  $G_{ij,k} = \partial G_{ij} / \partial x_k$ . Note that the summation convention will also apply to terms like  $M_{kk}$  or  $M_{kj} G_{ik,j}$ . The \* symbol denotes a **temporal convolution integral** and we partly drop the implicit time variable in the convolution formulas, e.g.,

$$\int_{\tau=-\infty}^t M(\xi, \tau) G(x, \xi, t - \tau) d\tau = M(\xi, t) * G(x, \xi, t) = M(\xi) * G(x, \xi)$$

## 2 Moment tensors: interpretation and decomposition

Moment tensors provide a general theoretical framework to describe seismic sources based on generalized force couples (Fig. 1). The moment tensor description is not restricted to earthquake sources, but covers also other types of seismic sources such as explosions, implosions, rock falls, landslides, meteorite terminal explosions (e.g. atmospheric), and mixed mode ruptures driven by fluid and gas injections. Thus, the concept of moment tensors is quite general and flexible making moment tensor inversions a very important tool in seismic source characterization. Moment tensors have the potential to substitute other, more traditional, source parameter estimations, such as e.g. magnitude or focal solutions from first motion polarities.

We denote a point source moment tensor by  $\mathbf{M}$ , a moment tensor density by  $\mathbf{m}$ . A moment tensor  $\mathbf{M}$  defines the strength of a seismic source in terms of its seismic moment, usually denoted by the scalar quantity  $M_0$ , and the radiation pattern of seismic waves. The moment tensor (3x3 matrix) is symmetric, i.e. it has six independent components. The diagonal elements represent linear vector dipoles, the off diagonal elements represent the force couples with arms (moment) (Fig. 1).

**Figure 1** The system of force couples representing the components of a Cartesian moment tensor. Diagonal elements of the moment tensor represent linear vector dipoles, while off-diagonal elements represent force couples with moment.

The moment tensor has components  $M_{ij}$  where  $i, j = 1, 2$ , or  $3$ . Often, a local geographic coordinate system is used to define a Cartesian system tensor, with positive  $x_1$  being north-, positive  $x_2$  eastward, and positive  $x_3$  being downward (NED). The NED coordinate system is used below to derive relations between the angles of a ruptured fault (strike and dip angle) and the dislocation direction on the rupture plane (rake angle).

A system commonly used in free-oscillation analysis is a local  $r$ - $\theta$ - $\phi$ -system, with  $r$ ,  $\theta$ ,  $\phi$  pointing upward, southward, and eastward (USE), respectively. This system is used for the routinely reported Global Centroid Moment tensors (Global CMT, formerly Harvard CMT). The geographic Cartesian tensor (NED) transforms by:

$$\begin{aligned} M_{rr} &= +M_{zz}, & M_{\theta\theta} &= +M_{nn}, & M_{\phi\phi} &= +M_{ee}, \\ M_{r\theta} &= +M_{nz}, & M_{r\phi} &= -M_{ez}, & M_{\theta\phi} &= -M_{ne}. \end{aligned} \quad (1)$$

Additional coordinate systems in use are ENU (e.g. Jost and Herrmann, 1989) and NWU (e.g. Box 8.3 in Lay and Wallace, 1995 and section 4.2.1 in Stein and Wysession, 2003). Different definitions lead to a different ordering and polarities of individual matrix components of the tensor. A wrong association may lead to mis-interpretation of components and fault directions. Therefore, the coordinate system should always be published together with the moment tensor solution.

With the exception of microseisms (ambient noise), earthquakes or explosions are the most common localized sources for seismic waves in the Earth. Other source such as tensile cracks, rock bursts or mass slope are significant sources close to the Earth's surface or in regions under high fluid overpressure (e.g. at volcanoes). All internal sources can be represented by a specific combination of generalized force couples (moment tensor components), which radiate at low frequencies the same waves as, for instance, the dislocation process on the geological fault. Having estimated a moment tensor, a decomposition and interpretation of the moment tensor is often needed to find the most appropriate geological or physical source process. In general, two concepts are followed when decomposing moment tensors:

- (1) the decomposition into physical (geological) source components to aid interpretation, for instance explosions, shear and tensile cracks or
- (2) the purely mathematical decomposition as a technique to simplify the inversion or numerical analysis.

We briefly introduce the source representations of the most elementary physical sources and then discuss different decompositions.

## 2.1 Elementary physical sources

### 2.1.1 The isotropic source (explosion and implosion)

$$\mathbf{M}_{iso} = \Delta V (\eta + 2N) \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

**Figure 2** Shape and radiation of the isotropic (volumetric) moment tensor

An explosion in a drill hole at depth is associated with abrupt volume change. In terms of pressure and force dipoles it is represented by an abrupt, isotropic pressure change and by means of three orthogonal linear force dipoles, respectively (see Fig. 2). The explosion (or implosion) radiates, theoretically, P waves with equal amplitude and polarity in all directions (isotropic source). S waves are not excited by the buried isotropic source. Most often, the polarity of the P wave radiation is plotted to visualize the radiation of the source. The lower hemisphere of a virtual sphere around the source is projected in a horizontal plane; examples and explanations are given in, e.g., chapter 3 of the NMSOP-2. The radiation pattern plot of an isotropic source is then a uni-colored sphere (black for explosion and white for implosion).

The only free parameter of the isotropic moment tensor,  $\mathbf{M}_{iso}$ , is the pre-factor of the unity matrix in Fig. 2, which defines the strength, or moment  $M_0 = tr = (M_{11} + M_{22} + M_{33})/3$ , of the isotropic source. Knowing  $M_0$  and the elastic constants  $N$  and  $\eta$  (see table 1) of the rocks at the source, the volume change  $\Delta V$  of the explosion or implosion source can be estimated by

$$tr = (M_{11} + M_{22} + M_{33}) / 3 = \Delta V (\eta + 2N) \quad (\text{explosion}) \quad (2)$$

Note that dislocation sources can also generate isotropic components in the radiation pattern of the source. The volume change associated with these sources is, however, different to equation (2) (see Müller, 1973, 2001) and given below. Note further that the moment of an explosion in the atmosphere has to be treated differently (e.g., Heimann et al., 2013).

### 2.1.2 The general dislocation source

**Figure 3a:** Dislocation of a shear crack with  $\mathbf{n}=(0,0,1)$  and  $\mathbf{D}_S=(0,-1,0)$ .

**Figure 3b:** Dislocation of a tensile crack with  $\mathbf{n}=(0,0,1)$  and  $\mathbf{D}_N=(0,0,1)$ .

A source associated with a planar crack and a dislocation vector  $\mathbf{D}$  in an arbitrary direction (shear as well as opening mode, see Fig. 3) may be termed a "general dislocation source". While tectonic earthquakes rupture in pure shear mode, rupture under the presence of fluids with high overpressure may involve an additional opening of the rupture plane. This may occur during magma- or fluid-intrusions, although the validity of observations of mixed-mode rupture are often debated among experts. The moment tensor of a general dislocation source is (eq. 3.21 in Aki and Richards, 2002)

$$M_{pq} = N A (n_p D_q + n_q D_p) + \eta A n_k D_k \delta_{pq} \quad (3)$$

The general dislocation source has five independent parameters. Equation (3) can be described in terms of strike ( $\phi$ ), dip ( $\delta$ ), rake ( $\lambda$ ), and the magnitudes of the shear ( $D_S$ ) and opening ( $D_N$ ) dislocation. If the moment tensor is defined in a NED system the relation to these parameters is (e.g., Dahm, 1998)

$$\begin{aligned} M_{11}/A &= -D_S N (\sin 2\phi \sin \delta \cos \lambda + \sin^2 \phi \sin 2\delta \sin \lambda) + D_N (\eta + 2N \sin^2 \phi \sin^2 \delta) \\ M_{12}/A &= +D_S N (\cos 2\phi \sin \delta \cos \lambda + 0.5 \sin 2\phi \sin 2\delta \sin \lambda) - D_N N \sin 2\phi \sin^2 \delta \\ M_{13}/A &= -D_S N (\cos \phi \cos \delta \cos \lambda + \sin \phi \cos 2\delta \sin \lambda) + D_N N \sin \phi \sin 2\delta \\ M_{22}/A &= +D_S N (\sin 2\phi \sin \delta \cos \lambda - \cos^2 \phi \sin 2\delta \sin \lambda) + D_N (\eta + 2N \cos^2 \phi \sin^2 \delta) \\ M_{23}/A &= -D_S N (\sin \phi \cos \delta \cos \lambda - \cos \phi \cos 2\delta \sin \lambda) - D_N N \cos \phi \sin 2\delta \\ M_{33}/A &= +D_S N \sin 2\delta \sin \lambda + D_N (\eta + 2N \cos^2 \delta) \end{aligned} \quad (4)$$

### 2.1.3 The shear dislocation source

The shear dislocation source is a special case of (4) if  $D_N=0$  and is usually associated with a tectonic earthquake. It has four independent parameters. The earthquake rupture is an expression of the rapid dislocation (described by the rake angle and slip) of the two surfaces of a geological fault (described by strike and dip angles) relative to each other. The rupture plane of an earthquake may become quite large if the earthquake is strong. For instance, a magnitude  $M_W$  6 earthquake may rupture a fault of several kilometer length. The ruptured portion of the geological fault is usually approximated by a plane of area  $A$ , e.g. with length  $L$  and width  $W$ . The earthquake source is therefore idealized by the physical model of a "planar shear crack" or "shear dislocation" source. In terms of forces, a shear crack can be represented by two perpendicular force dipoles with zero angular momentum. Therefore, the shear crack source is often termed "double couple" (DC). Fig. 3a gives an example of a shear dislocation on a horizontal plane with the associated moment tensor,

$$\mathbf{M} = A D_S N \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{bmatrix}, \quad (5)$$

where  $D_S$  is the average shear dislocation over the plane  $A$ . The seismic moment of the shear crack depends on the product between dislocation, the area of the ruptured plane and the shear modulus (see equation 3 and, e.g., equation 43 in IS3.1)

$$M_0 = \sqrt{(0.5 M_{pq} M_{pq})} = A D_S N \quad (6)$$

### 2.1.4 The tensile crack

For  $D_S=0$  in equation (4) we have a pure tensile crack. The tensile crack has only three independent parameters, since the direction of the dislocation vector is always perpendicular to the rupture plane (no rake angle defined). The principal axis moment tensor of the tensile crack of Fig. 3b, for instance, is given by

$$AD_N \begin{bmatrix} \eta & 0 & 0 \\ 0 & \eta & 0 \\ 0 & 0 & \eta + 2N \end{bmatrix} = (\eta + \frac{2}{3}N)AD_N \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} + \frac{2}{3}AD_N N \begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 2 \end{bmatrix} \quad (7)$$

The strength of the tensile crack may be defined in a similar manner as before. Calculating the volume change  $\Delta V$  can be of interest, for instance to estimate the volume of the intruded material. The decomposition in equation (7) shows how the volume change is related to the isotropic component of the tensile crack,  $\mathbf{M}_{\text{iso}}$ . Note this relation is different to equation (2) of the explosion source,

$$tr = (M_{11} + M_{22} + M_{33}) / 3 = \Delta V (\eta + 2N/3) \quad (\text{tensile crack}). \quad (8)$$

## 2.2 Decomposition into elementary sources

The decomposition of  $M_{pq}$  into physical sources is not unique. Several decompositions have been introduced depending on the source region and range of interpretations considered. The review paper by Jost and Herrmann (1989) gives an excellent overview and introduction to decompositions in use today. The paper describes the concepts of moment tensor decomposition, and how they can be coded by using dyadics. A brief summary is given below, and we refer to the original publication for details.

The moment tensor is first decomposed in its principal axis system

$$\mathbf{M} = \begin{pmatrix} a_{1x} & a_{2x} & a_{3x} \\ a_{1y} & a_{2y} & a_{3y} \\ a_{1z} & a_{2z} & a_{3z} \end{pmatrix} \begin{pmatrix} e_1 & 0 & 0 \\ 0 & e_2 & 0 \\ 0 & 0 & e_3 \end{pmatrix} \begin{pmatrix} a_{1x} & a_{1y} & a_{1z} \\ a_{2x} & a_{2y} & a_{2z} \\ a_{3x} & a_{3y} & a_{3z} \end{pmatrix} \quad (9)$$

Here,  $\mathbf{a}_i$  represent eigenvectors associated to eigenvalues  $e_i$ . The next step is to split the full tensor into an isotropic and a deviatoric tensor. If  $\mathbf{M}'$  represents the moment tensor in its principal axis system with eigenvalues  $e_i$  the decomposition is

$$\begin{pmatrix} e_1 & 0 & 0 \\ 0 & e_2 & 0 \\ 0 & 0 & e_3 \end{pmatrix} = \begin{pmatrix} tr & 0 & 0 \\ 0 & tr & 0 \\ 0 & 0 & tr \end{pmatrix} + \begin{pmatrix} e_1 - tr & 0 & 0 \\ 0 & e_2 - tr & 0 \\ 0 & 0 & e_3 - tr \end{pmatrix} \quad (10)$$

with  $tr = (e_1 + e_2 + e_3)/3$  being 1/3 of the trace of  $\mathbf{M}'$  and  $e'_k = e_k - tr$  being the eigenvalues of the deviatoric tensor.

**Figure 4** The two possibilities to decompose a full moment tensor, either into an isotropic and deviatoric tensor or into a general mixed-mode shear crack and a residual isotropic component. The deviatoric component can be further decomposed into different elementary sources.

The decomposition into  $\mathbf{M}_{iso}$  and  $\mathbf{M}_{dev}$  is unique. The  $\mathbf{M}_{iso}$  tensor radiates only P waves, Rayleigh waves and spheroidal normal modes with no directional preference. The deviatoric tensor ( $\mathbf{M}_{dev}$ ) often has no direct geological meaning and is therefore further decomposed into different geologically reasonable sources. Several decompositions have been suggested for the deviatoric tensor, for instance (e.g. Jost and Herrmann, 1989 and Fig. 4):

- a best double-couple (DC) and a CLVD,
- a strike slip, a pure dip slip and a vertical compensated linear vector dipole (vsCLVD),
- an isotropic source and a mixed mode double couple and tensile crack on the same crack (general dislocation source).

Geologically, the first decomposition maximizing the DC part is the most relevant one in most cases.

The first step in the decomposition is the calculation of eigenvalues and eigenvectors of the seismic moment tensor. If by definition a positive isotropic tensor is associated with volume expansion, the eigenvector of the largest eigenvalue gives the direction of the T (or tensional) axis; the one of the smallest eigenvalue the direction of the P (or compressional) axis, and the eigenvector of the intermediate eigenvalue gives the direction of the null axis. The demeaned absolute values of the eigenvalues can be used to estimate the proportional strength of the different source components of the deviatoric tensor (see Jost and Herrmann, 1989).

### 2.2.1 Decomposition into strike slip, dip slip DC sources and a vertical CLVD

Elementary tensors that fulfil orthogonality are sometimes used instead of Cartesian components (see e.g. Aki and Richards, 2002, Box 4.4, p. 112). One possible reason is to calculate Green's functions if the available codes that cannot handle single component moment tensor excitation. Another reason might be to easily incorporate constraints during inversion.

A possible decomposition into elementary tensors are: (1) a strike-slip double-couple ( $\mathbf{M}_1$ ), (2) a 90° dip-slip double-couple ( $\mathbf{M}_2$ ), (3) an isotropic tensor and (4) a vertical CLVD ( $\mathbf{M}_{v-clvd}$ ),

$$\mathbf{M} = \mathbf{M}_1(\phi_S) + \mathbf{M}_2(\phi_D) + \mathbf{M}_{iso} + \mathbf{M}_{v-clvd} \quad \text{with (in Cartesian system)}$$

$$\begin{aligned} \begin{pmatrix} M_{11} & M_{12} & M_{13} \\ M_{21} & M_{22} & M_{23} \\ M_{31} & M_{32} & M_{33} \end{pmatrix} &= \begin{pmatrix} -\frac{1}{2}(M_{22} - M_{11}) & M_{12} & 0 \\ M_{21} & \frac{1}{2}(M_{22} - M_{11}) & 0 \\ 0 & 0 & 0 \end{pmatrix} \\ &+ \begin{pmatrix} 0 & 0 & M_{13} \\ 0 & 0 & M_{23} \\ M_{31} & M_{32} & 0 \end{pmatrix} \\ &+ \frac{1}{3}(M_{11} + M_{22} + M_{33}) \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ &+ \frac{1}{3} \left( \frac{1}{2}(M_{22} + M_{11}) - M_{33} \right) \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}, \end{aligned} \quad (11)$$

The first and second term represent a strike-slip and pure dip-slip source, respectively, with strike angles  $\phi_S$  and  $\phi_D$ . The third term in equation (22) is the isotropic component and the forth term the vertical CLVD source. The strike slip source,  $\mathbf{M}_1$ , has a  $\pi$ -periodic azimuthal radiation pattern, the dip-slip  $\mathbf{M}_2$  a  $2\pi$ -periodic, and  $\mathbf{M}_{v-clvd}$  and  $\mathbf{M}_{iso}$  an azimuth-independent radiation pattern. SH- waves cannot resolve  $\mathbf{M}_{v-clvd}$  and  $\mathbf{M}_{iso}$ , SV-waves are not sensitive to  $\mathbf{M}_{iso}$ , while P-waves theoretically can resolve all elementary sources. The decomposition in equation (22) can be expressed in terms of strike, dip, and rake of the best double couple, the null-eigenvalue, and the trace of the tensor (Dahm, 1993).

### 2.2.2 Decomposition into a best double couple and a CLVD:

The decomposition, including the isotropic component of the full tensor, is commonly expressed by

$$\begin{bmatrix} e_1 & 0 & 0 \\ 0 & e_2 & 0 \\ 0 & 0 & e_3 \end{bmatrix} = tr \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} + (e_2 - tr) \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{bmatrix} + (e_1 - e_2) \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix} \quad (12)$$

If  $e_{min}$  and  $e_{max}$  are the smallest and largest absolute values of  $e'_k$  (assume  $|e'_3| \geq |e'_1| \geq |e'_2|$ ) and with  $F = e_{min} / e_{max} = e'_2 / e'_3$ , one may define  $100(1-2F)$  as the percentage of the double couple component (between 0% and 100%, see e.g. Dziewonski et al., 1981).

The DC component (last term in 12) has been described above. A CLVD source (middle term in 12) has no verified geological representation and is for crustal earthquakes often interpreted as source component representing the residual radiation from the best double couple source. The residual radiation may result from noisy data or from simplifying assumptions, as for instance from neglecting wave effects of a 3D Earth during the inversion. Therefore, a small or zero CLVD component is sometimes interpreted as a confirmation of the model assumption.

The decomposition of the deviatoric component into best DC and CLVD is commonly used in seismology. For instance, the source mechanism reported by nearly all seismic services are based on the decomposition into a best double couple and a CLVD component. A computer program for such a decomposition is described below.

### 2.2.3 Decomposition into an isotropic source and a mixed-mode shear-tensile crack:

The decomposition of the principal axis tensor into  $M_{iso}$  and a general dislocation crack is

$$\begin{bmatrix} e_1 & 0 & 0 \\ 0 & e_2 & 0 \\ 0 & 0 & e_3 \end{bmatrix} = tr \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} + (e_2 - tr) \begin{bmatrix} \frac{3}{2} \cos 2\phi - \frac{1}{2} & 0 & \frac{3}{2} \sin 2\phi \\ 0 & 1 & 0 \\ \frac{3}{2} \sin 2\phi & 0 & -\frac{3}{2} \cos 2\phi - \frac{1}{2} \end{bmatrix} \\ - \frac{3}{2}(e_2 - tr) \tan 2\phi \begin{bmatrix} \sin 2\phi & 0 & \cos 2\phi \\ 0 & 0 & 0 \\ \cos 2\phi & 0 & -\sin 2\phi \end{bmatrix}, \quad (13)$$

with  $\tan^2 \phi = \frac{-3(e_2 - tr) + e_3 - e_1}{3(e_2 - tr) + e_3 - e_1}, e_2 - tr \neq 0$ .

where the angle  $\phi$  defines the angle of the dislocation plane measured against the T axis in the plane given by the T and P axis (P and T are interchanged in case of contraction) (e.g. Dahm, 1993; Dahm and Brandsdottir, 1997). Another formulation of mixed-mode crack decomposition is given by Vavryčuk (2001).

## 2.3 Computer programs for decomposition

Computer programs for decomposition were written by Jost and distributed in Volume VIII of the software package “Computer Programs in Seismology” (see R. Herrmann, Saint Louis University <http://www.eas.slu.edu/People/RBHerrmann/ComputerPrograms.html>). Another computer package is provided with the python tool ”MoPaD” (Krieger and Heimann, 2012; <http://www.larskrieger.de/mopad/>), which can be used for decomposition, projection and the plotting of moment tensors. MoPaD can be easily combined with GMT plotting tools (<http://gmt.soest.hawaii.edu>).

The following examples are derived using MOPAD. On 19 March 2013 a  $M_L$  4.2 earthquake struck the Polish mine district close to the Rudna copper mine. 19 mine workers were trapped in the mine at 850 m depth for several hours due to rock bursts affecting parts of the underground tunnels. A centroid moment tensor inversion (0.07-0.1 Hz) using broadband regional stations retrieved a seismic moment of  $M_W$  3.8 ( $M_0=5.3E14$  Nm) at a source depth of

about 1 km (Whidden et al., 2013; Rudzinski and Lizurek, pers. communication). The NED Cartesian moment tensor is decomposed into an isotropic and deviatoric part,

$$\begin{aligned}\hat{\mathbf{M}} &= 5.3 \cdot 10^{14} Nm \begin{pmatrix} -0.40 & +0.01 & -0.10 \\ +0.01 & -0.43 & +0.01 \\ -0.10 & +0.01 & -1.00 \end{pmatrix} \\ &= 5.3 \cdot 10^{14} Nm \begin{pmatrix} -0.61 & & \\ & -0.61 & \\ & & -0.61 \end{pmatrix} + 5.3 \cdot 10^{14} Nm \begin{pmatrix} +0.21 & +0.01 & -0.10 \\ +0.01 & +0.18 & +0.01 \\ -0.10 & +0.01 & -0.39 \end{pmatrix}\end{aligned}$$

The radiation pattern is plotted in a lower hemispherical projection (Fig. 5a, and chapter 3 of NMSOP-2 for explanations on the type of plots). The isotropic component is negative (implosion) and covers 60% of the moment of the full tensor.

**Figure 5a** Lower hemispherical projection of the P-wave radiation (stereographic) of the Rudna mine 2013  $M_W$  3.8 moment tensor solution

**Figure 5b** Lower hemispherical projection (stereographic) of the 13 Oct. 2013  $M_W$  6.6 Gulf of California moment tensor solution.

Apparently, the relatively slow collapse of void space in the mine building dominates the long period wave radiation and gives the major contribution of the seismic moment. The 40% deviatoric source component can be decomposed in a best double couple (DC) and a CLVD component, where the DC covers only about 13% of the size of the deviatoric tensor. The low frequency radiation pattern can therefore be interpreted in terms of an isotropic and CLVD component, where the CLVD is roughly vertically oriented. The source process may be interpreted in terms of a tensile crack as given in equation (23), by e.g.

$$AD_N \begin{pmatrix} \eta & 0 & 0 \\ 0 & \eta & 0 \\ 0 & 0 & \eta + 2N \end{pmatrix} \approx 5.3 \cdot 10^{14} Nm \begin{pmatrix} -0.4 & 0 & 0 \\ 0 & -0.4 & 0 \\ 0 & 0 & -1.00 \end{pmatrix}$$

and thus

$$\begin{aligned}
AD_N &= 5.3 \cdot 10^{14} \text{ Nm} \cdot 0.5(-1.0 + 0.4)/25 \cdot 10^9 \text{ N/m}^2 \approx 6360 \text{ m}^3 \\
\eta &= -0.4 \times 5.3 \cdot 10^{14} \text{ Nm} / -6360 \text{ m}^3 \approx 33 \text{ GPa} \\
\nu &= \frac{\eta}{2(\eta + N)} \approx 0.28
\end{aligned}$$

The collapsed volume  $AD_N$  can be used to estimate the area affected by the collapse if the average height of the galleries in the mine is specified. For instance, assuming the average height of the gallery is 5m, the estimated area is about 35m x 35m. The estimated Poisson ratio of 0.28 and the derived Lamé's parameter may be used to check the consistency of the source interpretation with expected rock properties. Ford et al. (2008) studied a mine collapse event of a coal mine in Utah and estimated a vertical crack component of comparable relative strength.

The second example concerns the moment tensor solution of an  $M_w$  6.6 earthquake in the Gulf of California that occurred on 13 October 2013 at a depth of 16 km. The global moment tensor solution in an USE system is (GFZ solution) is

$$\hat{\mathbf{M}} = 1 \cdot 10^{18} \text{ Nm} \begin{pmatrix} -0.59 & -2.52 & -1.72 \\ -2.52 & -7.58 & -0.95 \\ -1.72 & -0.95 & +8.16 \end{pmatrix}$$

The isotropic component is constraint to zero during inversion. The seismic moment is estimated to as 9.1E18 Nm. The DC component of the solution is 99%, meaning that the rupture can be interpreted as pure shear crack, in this case a dominant left lateral strike slip mechanism (see Fig. 5b) with strike, dip and rake of the two nodal planes of

$$\begin{aligned}
\text{plane 1: } & \Phi = 133^\circ, \quad \delta = 69^\circ, \quad \lambda = -173^\circ \\
\text{plane 2: } & \Phi = 40^\circ, \quad \delta = 84^\circ, \quad \lambda = -20^\circ
\end{aligned}$$

## 2.4 Displaying different moment tensor components

Displaying the elementary source components in a simple graph is not trivial. Hudson et al. (1989) and Riedesel and Jordan (1998) suggested diagrams for this purpose. The Hudson et al. (1989) plot is now often used. See Tape and Tape (2012) for a geometric comparison of source-type plots. Figure 6 displays the Hudson-type plot for the two moment tensors discussed in 2.3. The pure double couple moment tensor is centered at the origin and indicates a pure DC moment tensor. The Rudna mine solution is localized in the lower half-space indicating negative isotropic source components. It is very close to a pure linear dipole solution, which further shows that the source is close to a pure collapsing crack solution. Opening cracks would appear in the positive half-space close to the positive dipole marker. Pure explosions and isotropic implosions events appear on the vertical axis of the plot frame at the points marked by +ISO and -ISO, respectively.

**Figure 6** Hudson plot for displaying source components. The filled circles represent the source components of the two examples in 2.3.

### 3 Moment tensor representations: basic relations

A moment tensor representation is a formula to explain the theoretical relation between ground motions at the stations and the moment tensor at the source. This usually considers the dynamic ground motion and the wave radiation pattern in the far field. However, the theory also explains static and near field (near source) ground motions as well as source-generated strain and stress variations in the Earth. Knowing the moment tensor representation (the forward problem),  $\mathbf{M}$  can be obtained by inverting one or several of the observed field variables. Moment tensor inversion requires the availability digital time series of observed data, e.g. full seismograms or at least P and S phases, measured un-clipped on linear and predictable acquisition systems (e.g. calibrated systems), and the calculation or availability of accurate synthetic seismograms of the Earth (i.e. Green's functions, denoted by  $\mathbf{G}$ ). Therefore, moment tensor inversion is more demanding from an observational and computational point of view.

**Figure 7** Geometry of the problem. The Green's tensor  $\mathbf{G}$  describes the impulse response of the Earth at station  $\mathbf{x}_0$  for a force excitation at  $\xi_0$ . The point source is described by moment tensor  $\mathbf{M}$  and source time function  $h(\tau)$ . The ground motion at the station,  $u(t)$ , differs from the source excitation because of the filter effect of the Earth. The blue line indicates the ray path. The ray angle  $i$  is measured against the vertical; at the source  $i_0$  defines the take-off angle. Note that the global coordinate system is source centered and that the 1-direction of both systems is defined by the source station path.

The basic theory and representation of seismic sources is outlined in chapter 3 of the NMSOP-2 and in IS3.1. We build on this theory and concentrate on the point source moment tensor representation of ground displacement (see equation 21 in IS3.1, neglecting the single force term)

$$u_n(\mathbf{x}, t) = M_{pq}(\boldsymbol{\xi}, t) * \frac{\partial}{\partial \xi_q} G_{np}(\mathbf{x}, \boldsymbol{\xi}, t)|_{\xi_0} = M_{pq}(\boldsymbol{\xi}, t) * G_{np,q}(\mathbf{x}, \boldsymbol{\xi}, t) \quad (14)$$

Equation (14) may alternatively be given in the frequency domain. The components of the ground displacement at location  $\mathbf{x}$  are declared by  $u_n$ .  $\mathbf{M}$  is the moment tensor of the seismic point source at location  $\boldsymbol{\xi}$ , and  $G_{np,q}$  are spatial derivatives with respect to  $\xi_k$  of components of the Green's tensor  $\mathbf{G}$ . The Green's tensor can be viewed as a structural term defined between  $\boldsymbol{\xi}$  and  $\mathbf{x}$  which describes all wave propagation effects including the elastostatic response of the Earth due to a single force delta-excitation at point  $\boldsymbol{\xi}$  measured at point  $\mathbf{x}$  (Fig. 7). The first index of  $G_{np}$  gives the direction of the ground motion at the station, and the second index gives the direction of the force at the source. It is common practice to denote the two independent coordinate systems of the receiver  $(\mathbf{x}, t)$  and the source point  $(\boldsymbol{\xi}, \tau)$  as independent variables in  $\mathbf{G}$ . Note that the following equivalence is used  $G(\mathbf{x}, t; \boldsymbol{\xi}, \tau) = G(\mathbf{x}, t - \tau; \boldsymbol{\xi}, 0)$  (e.g., Aki and Richards, 2002). The components of the Green's tensors are often named Green's functions and may represent full seismograms. Later, we will introduce elementary seismograms as a special component of derivatives of the Green's tensor.

Equation (14) can be used to invert for moment tensors. Necessary condition is that observed seismograms have been deconvolved to ground displacement, velocity or acceleration (see IS11.1) and that Green's functions have been calculated between the source and receiver point assuming an appropriate Earth model. We will give examples of Green's function calculation below. Equation (14) can be written in matrix form, e.g. by considering the discrete form of the multichannel convolution integral (e.g., Krieger, 2011). We introduce notations  $\mathbf{d}$ ,  $\mathbf{G}'$  and  $\mathbf{y}$  to indicate that the data and model vectors are not directly the tensor components defined in (14). They represent channels from more than one station ( $R$  is the maximal channel number), either in displacement, velocity or acceleration, and the derivatives or Green's functions. In the time domain,  $\mathbf{d}$ ,  $\mathbf{G}'$  and  $\mathbf{y}$  further contain individual time samples (denoted by subscript index of time variables) at the different components and at different stations. We find

$$\begin{bmatrix} d_1(t_0) \\ d_2(t_0) \\ d_3(t_0) \\ \vdots \\ d_R(t_0) \\ d_1(t_1) \\ d_2(t_1) \\ \vdots \\ \vdots \end{bmatrix} = \begin{bmatrix} G'_{11}(t_0, \tau_0) & G'_{21}(t_0, \tau_0) & \dots & G'_{11}(t_0, \tau_1) & G'_{21}(t_0, \tau_1) & \dots \\ G'_{12}(t_0, \tau_0) & G'_{22}(t_0, \tau_0) & \dots & G'_{12}(t_0, \tau_1) & G'_{22}(t_0, \tau_1) & \dots \\ G'_{13}(t_0, \tau_0) & G'_{23}(t_0, \tau_0) & \dots & G'_{13}(t_0, \tau_1) & G'_{23}(t_0, \tau_1) & \dots \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots \\ G'_{1R}(t_0, \tau_0) & G'_{2R}(t_0, \tau_0) & \dots & G'_{1R}(t_0, \tau_1) & G'_{2R}(t_0, \tau_1) & \dots \\ G'_{11}(t_1, \tau_0) & G'_{21}(t_1, \tau_0) & \dots & G'_{11}(t_1, \tau_1) & G'_{21}(t_1, \tau_1) & \dots \\ G'_{12}(t_1, \tau_0) & G'_{22}(t_1, \tau_0) & \dots & G'_{12}(t_1, \tau_1) & G'_{22}(t_1, \tau_1) & \dots \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots \end{bmatrix} \cdot \begin{bmatrix} y_1(\tau_0) \\ y_2(\tau_0) \\ \vdots \\ y_6(\tau_0) \\ y_1(\tau_1) \\ y_2(\tau_1) \\ \vdots \\ \vdots \end{bmatrix}$$

or equivalently

$$\mathbf{d} = \mathbf{G}' \mathbf{y} . \quad (15)$$

Equation (15) is given in the form of a linear system of equations, and represents a discrete form of the multichannel convolution integral.  $\mathbf{d}$  and  $\mathbf{y}$  are the ‘data’ and ‘model’ vector, respectively, and  $\mathbf{G}'$  represents the coefficient matrix. Dimension of  $\mathbf{d}$ ,  $\mathbf{y}$  and  $\mathbf{G}'$  are determined by the length of the data seismograms, the number of channels and the length of the assumed source time function ( $N_\tau$ ), and can easily grow large. The data vector  $\mathbf{d}$  consists of individual seismograms measured at different stations. These may be full seismograms, usually band-pass filtered, or windowed traces of specific wave phases. The coefficient matrix  $\mathbf{G}'$  is build from derivatives of the Green’s functions (filtered and processed in the exact same way as the data). The components of the model vector  $\mathbf{y}$  contain the  $6 \times N_\tau$  unknowns and are formed by holomorphic mapping of the moment tensor components into a model vector  $\mathbf{y}$ , e.g.

$$\begin{aligned} y_1 &= M_{11}, & y_2 &= M_{12}, & y_3 &= M_{22}, \\ y_4 &= M_{13}, & y_5 &= M_{23}, & y_6 &= M_{33}, \end{aligned} \quad (16)$$

Equation (15) is typically solved by the least squares (LS) inversion technique, either in the time domain (e.g. multichannel Wiener filtering described, e.g., in Wiggins and Robinson, 1965; Sipkin, 1982) or in the frequency domain (e.g. generalized inverse using singular value decomposition, e.g., Menke 1989).

The system (15) is over-determined, i.e. it has more independent equations (data) than unknowns, if for instance enough ground motion measurements are available from different distances and station azimuths, such that the azimuthal data coverage is sufficient to resolve the radiation pattern of the source. Also, the assumed source time duration should be much smaller than the length of the seismograms (or is parameterized by simple functions). Equation (15) is written for 27 independent components of the spatial derivatives of the Green’s tensor (3<sup>rd</sup> order tensor, i.e.  $3 \times 3 \times 3$  components) if three component seismograms are inverted. Green’s functions in this general formulation would consider near and far field terms. The time history of each moment tensor component is assumed to be independent. Altogether, this leads to a large number of unknowns, which are possibly difficult to resolve. Additionally, the choice of waves types selected (near field, far field, body wave phases, surface waves, etc.), the frequency range, the type of applied filters as well as the weighting scheme applied to the equations may influence the outcome of the inversion. Therefore, the equations implemented in practice are often modified in comparison to equation (15). For instance, the number of unknowns is reduced, e.g. by simplifying the time history of the moment tensor or by specifying the type of source mechanism (e.g. non-explosive). The number of Green’s functions is reduced by taking advantage of Earth model symmetries and/or by neglecting near field terms. Additionally, damping and linear or non-linear constraints may be considered. This leads to modified schemes and equations.

We discuss representations of the source time and moment rate function, the concept of joint inversion point source moment tensors and centroid locations, the simplified representation formulas for a layered Earth model and for the far field, formulas for amplitude spectra and specific representations if only body waves or peak amplitudes are used. Some words are given for the relative moment tensor inversion, the normal mode summation and how to calculate Green’s functions in practice.

### 3.1 Resolving the time dependency of moment tensors

The components of the moment tensor are time dependent and are related to the time history of slip (or rupture) at the source. Equation (15), or the equivalent form in the frequency domain, invert for the independent time function of each moment tensor component. The problem is often ill-posed and source-time functions vary a lot between the components. Different approaches have been suggested to stabilize the source time function inversion.

Often, a homogeneous rupture process is assumed, so that each moment tensor component has the same time history, e.g.  $h(t)$ . Then, it is useful to factorize the time history and leave only the magnitude of the time-independent scaling factors of the moment tensor components, e.g. denoted by  $\hat{M}_{pq}$ , leading to

$$M_{pq}(t) = h(t)\hat{M}_{pq} \quad \text{with} \quad h(t) = \begin{cases} 0 & \text{for } t \leq 0 \\ 1 & \text{for } t > T_d > 0 \end{cases} \quad (17)$$

where  $T_d$  is the duration of the ramp-like source time.

A common simplification is to use only far-field recordings. The far field displacement scales with the time derivative of  $h$ , i.e.  $\dot{h} = dh/dt$ , often denoted as moment rate function.

Near field Green's functions represent the component of the Green's functions, which remain zero at all times far from the source. Near and far field terms can be derived by equating the derivative of  $\mathbf{G}$  with respect to the source coordinate  $\xi_k$ , and separating the terms attenuating faster and slower. Lets assume  $\xi$  as independent variable. Both other intrinsic variables of  $G$ ,  $x$  and  $t-\tau$ , depend on the distance to the source, which itself depends on  $\xi$ . The derivative of  $G$  is equated by

$$\frac{\partial}{\partial \xi_q} G_{np}(\mathbf{x}, t') = \frac{\partial G_{np}}{\partial x_l} \frac{\partial x_l}{\partial \xi_q} + \frac{\partial G_{np}}{\partial t} \frac{\partial t'}{\partial \xi_q} = G_{npq}^{(n)} + \dot{G}_{npq}^{(f)} \quad (18)$$

$t'$  is the retarded time at the station. For body waves,  $\partial t'/\partial \xi_k$  are components of the slowness vector of the phase. The first and second term are associated with the near-field and far-field term of  $\mathbf{G}$ , associated by superscripts (n) and (f). Inserting (17) and (18) into (14) leads to the far field moment tensor representation as

$$u_n^{(f)}(\mathbf{x}, t) \approx \hat{M}_{pq} h(t) * \dot{G}_{npq}^{(f)}(\mathbf{x}, t) = \hat{M}_{jk} \dot{h}(t) * G_{npq}^{(f)}(\mathbf{x}, t) \quad (19)$$

Equation (19) shows that displacement in the far field depends on moment rate function and the far field Green's functions excited by a unit step at the point source. This is a general result, which explains that the far field body wave pulses from earthquakes are related to time derivatives of the source time function at the source. If the source time function is an ideal step function, the far field pulse is a pulse like. If it is a ramp function of duration  $T_d$ , the expected body wave pulse has the shape of a boxcar function of duration  $T_d$ .

**Figure 8** The Earth is described as a linear system with impulse response  $G(t)$  (Green function). The ground motion response  $u(t)$  at the station depends on  $G(t)$  and the excitation  $h(t)$  at the seismic source (input). The shape of the source radiation, i.e. the moment tensor, has been set unity in the 1D sketch (i.e. representing an explosive source as special case).

The interrelation between source time function  $h(t)$  and displacement  $u(t)$  can also be understood as a filtering effect (Fig. 8).  $h(t)$  is the input signal. The linear filter is represented by  $G(t)$  as the elastic response of the Earth. The ground displacement at the station,  $u(t)$ , is the filter output, and is equated as a convolution integral between the input and the filter.

Before we give some examples on how to estimate moment rate functions in practice, we use equation (19) to derive and explain the centroid time  $\tau_0$ . The centroid time is a point source parameter, defining the centre time of the wave radiation process. It is defined from the long period approximation of (19), which is valid if the period is  $T > T_d$ . A Taylors series expansion of the Green's tensor in (19) around the centroid  $\tau_0$  leads to

$$u_n^{(f)}(\mathbf{x}, t) \approx \hat{M}_{pq} G_{npq}^{(f)}(\mathbf{x}, t - \tau_0) + \hat{M}_{pq} \dot{G}_{npq}^{(f)}(\mathbf{x}, t - \tau_0) \int_0^\infty \dot{h}(\tau)(\tau - \tau_0) d\tau + \dots$$

The convolution integral is written in explicit form. The centroid time  $\tau_0$  is then defined in such a way that the integral on the right-hand side vanishes (see Fig. 9 and Nabelek, 1984). For low-pass filtered seismograms the other higher order terms can be omitted, which gives the temporal (and spatial) point source representation of ground displacement as

$$u_n^{(f)}(\mathbf{x}, t) = \hat{M}_{pq} G_{npq}^{(f)}(\mathbf{x}, t - \tau_0) \quad . \quad (20)$$

Note that the far field displacements in (20),  $u^{(f)}$ , becomes zero a long time after waves have passed through the observing point since Green's functions in the far field are zero for large  $t$ .

Although equation (20) is appropriate if the seismograms are low-pass filtered, many authors try to resolve the time history  $h(t)$  or, at least, the source duration. Although we have not yet strictly defined the spatial point source, we note that attempts to retrieve the source time functions of a spatial point source are not always useful. This is because a spatial point source moment tensor representation requires wavelengths larger than the size of the rupture plane. Resolving the source time is then only possible if the rise-time of the slip function at a single slip patch is longer than the rupture duration.

A common method to resolve the time dependency of  $h(t)$  uses the linear representation in (15) and a two step inversion approach. Examples are given by Vasco (1989) or Cesca and Dahm (2007). The first inversion step estimates the independent time function of each

moment tensor component  $y_k$ . This may be performed either in the time or in the spectral domain. The second inversion step aims to retrieve the dominant common time history  $h(t)$  presented in each component. A singular value decomposition of the matrix formed by the time dependent moment tensors is calculated. The matrix of orthogonal eigenvectors are weighted by the eigenvalues. The dominant time history common to all source components is then represented by the system of equations, which considers only the largest eigenvalue and sets all other eigenvalues to zero. More details can be found in e.g. Vasco (1989), Cesca and Dahm (2007) or Vavryczuk and Kühn (2012).

Other methods use smooth parameterizations of the moment rate function and solve directly the non-linear inverse problem for  $dh/dt$  (equation 19). The two most common parameterizations are a series of boxcars or overlapping triangles (e.g., Tsai et al., 2005, for the Great Sumatra-Andaman earthquake). The boxcar parameterization and the iterative, linearized least-squares inversion is described in, e.g., Tanioka and Ruff (1997) or Lay and Wallace (1995).

Tocheport et al. (2007) follow a different approach, which uses a stack of time-shifted and weighted body wave pulses at different stations minimized against an average source time function. The time shifts and weights are parameter of the inversion, which is solved by simulated annealing. Since the method requires isolated body waves, the method can only be applied to deep and intermediate earthquakes.

If a point source inversion is performed and seismograms are lowpass filtered, the details of the source time function of most earthquakes cannot be resolved. In such a case, often, only a rise time of the source time function is estimated (equivalent to the duration of a boxcar moment rate function, or other simple shapes). For instance, different rise times are tested in a grid search approach and the one leading to the least residuals in the waveform inversion is finally chosen (e.g., Heimann, 2011). The grid search approach can be used to determine station-related, apparent source durations after a best point source moment tensor is estimated. This may be of interest for a quick and rough analysis of rupture directivity, i.e. to separate fault and auxiliary plane and to distinguish the direction of rupture. For instance, Cesca et al. (2010b) suggest to keep the seismic moment and source mechanism of the point source solution and to invert for the source duration at each station. The apparent source time functions can then be interpreted in terms of a simplified kinematic rupture model. Zhang et al (2013) use an iterative deconvolution and stacking method to retrieve apparent source time functions for the purpose of rapid source imaging.

### 3.2 Representation of the centroid location (centroid moment tensor inversion)

Equation (20) was already defined for a centroid time  $\tau_0$  as origin time to calculate Green's functions. Similarly to the derivation of  $\tau_0$  spatial centroid coordinates  $\xi_0$  can be derived by means of a Taylors series expansion of Green's functions. The problem is sketched in Fig. 9, a detailed derivaton can be found in, e.g., Nabelek (1984). Often, the hypocenter from the location of first phase arrivals is taken as a first approximation of the centroid. However, the hypocenter, which represents the point of rupture initiation (nucleation), may be tens or hundred kilometer away from the slip centroid if the earthquake was very large. Thus, the Green's functions calculated for the parameters of the hypocenter may be wrong or at least have large phase shifts relative to observed data. This may bias the moment tensor results. Three approaches are in use to reduce the possible bias.

The first workaround, instead of estimating a best centroid position, is to introduce ad hoc static phase shifts to the observed waveforms before inversion, for instance by cross correlation between observed and synthetic data. To first order the phase shifts may correct the mislocation of the centroid and leave the amplitudes of seismograms unchanged. However, the estimation of phase shifts is a tricky task and may easily lead to undesired (incorrect) shifts, especially if automatic processing is performed.

The more rigorous approach is to estimate the centroid during the inversion, which is named a centroid moment tensor inversion. The inverse problem has four additional unknowns (moment tensor components plus spatial and temporal coordinates) and becomes nonlinear. The centroid inversion can be setup similar to the Geiger method of a standard location (IS11.1). The nonlinear equations are approximated by the first linear terms of a Taylor series expansion around a starting solution. For instance, the hypocenter is used as starting location. The inversion for changes of source parameters is linear and solved employing a standard LS method. The solution is used to improve the starting solution, and the process is iteratively repeated until the changes become very small or the residuals are minimal. Since the equations for moment tensor inversion are linear, the moment tensor inversion itself is straight forward will always find an optimal solution. However, Green's functions have to be re-calculated for the updated centroid location during each iteration. The centroid location problem is nonlinear and will have the same problems of non-uniqueness and non-convergence as standard earthquake location, especially since waveforms instead of first motions are fitted. In practice, depth centroid moment tensor inversion is thus often estimated by a grid search over a depth range in fixed steps combined with additional empirical static phase shifts at each station (limited to a fixed range of allowed phase shifts). Considering static phase shifts in addition to centroid depth location has the advantage that the impacts from incorrect Earth models or unaccounted 3D structure are reduced.

**Figure 9** a) Schematic sketch of an earthquake rupture and the definition of hypocenter, centroid, rupture plane and slip. Rupture and slip is parameterized by the moment tensor density,  $\mathbf{m}$ , and its time history  $h(t)$ . b) 1D visualization of spatial and temporal centroid coordinates to balance the third order spatial ( $\int_V (\xi_k - \xi_{0k}) m_{ij} dV = 0$ ) and temporal moments ( $\int_\tau (\tau - \tau_0) (dh/d\tau) d\tau = 0$ ) to zero (principle is comparable to finding the center of gravity).

The third approach to handle an unknown centroid location is to invert amplitude spectra in the first iteration. Amplitude spectra discard the phase information and are therefore less affected by incorrect centroid locations and Earth models. However, the amplitude spectra

cannot resolve the polarity of the source mechanism. This means an amplitude spectra inversion alone cannot resolve whether the seismic source was an explosion or an implosion, or whether the earthquake was a thrust or a normal faulting event. However, strike and dip of the fault and auxiliary planes are resolved. In order to resolve the polarity ambiguity either additional information is added to the inversion (e.g. first motion polarities), or the inversion is performed in a two-step approach, where amplitude spectra are inverted in the first iteration, and time-shifted full waveforms are considered in addition in a 2<sup>nd</sup> iteration. The 2<sup>nd</sup> step may keep strike and dip of the first solution fixed. We will further discuss this third approach below.

### 3.3 Representation in a layered Earth model

If a layered Earth model is assumed, only 10 instead of 27 Green's functions are needed. If additionally only far field seismograms (see IS3.1) are analyzed, the number of required Green's functions is further reduced to 8. If only body wave phases are inverted (ray-theoretical description), the number of Green's functions further reduces to 3 greatly simplifying the inverse problem. The reduced set of specific Green's functions are often combinations of the original Green's functions defined under specific azimuth angles and are called elementary seismograms. We briefly outline the redundancy of Green's tensors and the definition of elementary seismograms.

Fig. 7 indicates two coordinate systems, a local one defined at the source location and a global one for the source-station geometry. Sensor components of seismometers are usually measured in an east–north–up system. The sensor components in the representation formulas and in Fig. 7 should be defined in the curvilinear, global source-centered system, e.g. by radial, transversal and down directions (distance  $r$ , azimuth  $\phi$  and depth  $z$ ). However, the moment tensor is usually defined for a local Cartesian system. At the pole, the local NED system, with  $x=N$ ,  $y=E$  and  $z=down$ , has the same directions as the local spherical system. Only in the specific case where the great circle path between source and receiver is along a meridian, i.e. the station is under azimuth  $\phi'=0$ , the local and global directions would be identical. We denote the Green's tensor in this specific case by  $\mathbf{G}^0$ . If the media is invariant to azimuthal rotations around  $z$ , e.g. layered Earth models, the Green's tensor can be given as a rotated version of  $\mathbf{G}^0$ . We define unprimed and primed indices to define the unrotated (NED) and rotated azimuth directions.  $R(\phi')$  declares a matrix describing rotation with angle  $\phi'$  around the  $z$  direction. Using tensor rotation the Green's tensor in the source-station system can be equated from  $\mathbf{G}^0$

$$G_{n'p',q'} = R_{p'p}(\phi') R_{q'q}(\phi') G_{n'p,q}^0 = R_{p'p}(\phi') G_{n'p,q}^0 R_{qq'}(-\phi') \quad (21)$$

At  $\phi'=0$  the P-SV motion can only be excited by moment tensor components  $M_{xx}$ ,  $M_{zz}$ ,  $M_{xz}$ ,  $M_{zx}$  and  $M_{yy}$  (note that  $M_{yy}$  comes into play only for near field displacements). Contrary, SH motion can only be excited by moment tensor components  $M_{xy}$  and  $M_{yx}$ . This reduces the zero azimuth tensor to

$$\mathbf{G}_r^0 = \begin{pmatrix} G_{rx,x}^0 & 0 & G_{rx,z}^0 \\ 0 & G_{ry,y}^0 & 0 \\ G_{rz,x}^0 & 0 & G_{rz,z}^0 \end{pmatrix}$$

$$\mathbf{G}_\varphi^0 = \begin{pmatrix} 0 & G_{\varphi x,y}^0 & 0 \\ G_{\varphi y,x}^0 & 0 & G_{\varphi y,z}^0 \\ 0 & G_{\varphi z,y}^0 & 0 \end{pmatrix}$$

$$\mathbf{G}_z^0 = \begin{pmatrix} G_{zx,x}^0 & 0 & G_{zx,z}^0 \\ 0 & G_{zy,y}^0 & 0 \\ G_{zz,x}^0 & 0 & G_{zz,z}^0 \end{pmatrix}$$

Thus, in layered media, equation (14) reduces to

$$\begin{aligned} u_{r'} &= +g_1 \star (M_{xx} \cos^2 \varphi + M_{yy} \sin^2 \varphi + M_{xy} \sin 2\phi) \\ &\quad +g_9 \star ((M_{xx} \sin^2 \varphi + M_{yy}) \cos^2 \varphi - M_{xy} \sin 2\phi) \\ &\quad +g_2 \star (M_{xz} \cos \phi + M_{yz} \sin \phi) \\ &\quad +g_3 \star M_{zz} \\ u_{\varphi'} &= +g_4 \star \left( \frac{1}{2} (M_{yy} - M_{xx}) \sin 2\varphi + M_{xy} \cos 2\varphi \right) \\ &\quad +g_5 \star (M_{yz} \cos \varphi - M_{xz} \sin \varphi) \\ u_{z'} &= +g_6 \star (M_{xx} \cos^2 \varphi + M_{yy} \sin^2 \varphi + M_{xy} \sin 2\phi) \\ &\quad +g_{10} \star ((M_{xx} \sin^2 \varphi + M_{yy}) \cos^2 \varphi - M_{xy} \sin 2\phi) \\ &\quad +g_7 \star (M_{xz} \cos \phi + M_{yz} \sin \phi) \\ &\quad +g_8 \star M_{zz} \end{aligned} \tag{22}$$

with the following elementary seismograms

$$\begin{aligned} g_1 &= G_{r'x,x}^0 & g_2 &= G_{r'x,z}^0 + G_{r'z,x}^0 & g_3 &= G_{r'z,z}^0 \\ g_4 &= G_{\varphi'x,y}^0 + G_{\varphi'y,x}^0 & g_5 &= G_{\varphi'y,z}^0 + G_{\varphi'z,y}^0 & & \\ g_6 &= G_{z'x,x}^0 & g_7 &= G_{z'x,z}^0 + G_{z'z,x}^0 & g_8 &= G_{z'z,z}^0 \\ g_9 &= G_{r'y,y}^0 & g_{10} &= G_{z'y,y}^0 & & \end{aligned} \tag{23}$$

Equation (22) and (23) represent the system of equations for a layered Earth. Only ten independent elementary seismograms  $g_1 - g_{10}$  are needed, of which components  $g_9$  and  $g_{10}$  contain only near field terms (e.g. Müller, 1985) and are neglected in most moment tensor studies of earthquakes.

### 3.4 Representation for body waves (peak amplitudes and amplitude ratios)

The number of independent Green's functions is further reduced if a ray theoretical approximation is valid, for instance, if we consider only far field body wave phases associated with a specific ray path (e.g., qP and qS phases). The ray direction (ray angle  $i$ , see Fig. 7), is related to the horizontal and vertical components of the slowness vector by

$$(s_x, s_y, s_z) = (s_x, 0, s_z) = |s| (\sin(i), 0, \cos(i)). \quad (24)$$

If we consider in the far field that  $M_{pq}(\xi_0) * G_{np,q}(x, \xi_0) \approx dM(\xi_0)/dt * G_{np}(x, \xi_0) s_q + O(\text{near field terms})$  (e.g. Dahm, 1996), the rotation of the zero azimuth Green's tensor leads to further simplified moment tensor representation for the three modes of body waves phases:

for qP

$$\begin{aligned} G_{z'x}^0 s_x &= g_6 = I_e^P \sin^2 i \\ G_{z'x}^0 s_z + G_{z'z}^0 s_x &= g_7 = I_e^P 2 \sin i \cos i \\ G_{z'z}^0 s_z &= g_8 = I_e^P \cos^2 i, \end{aligned}$$

for qSV

$$\begin{aligned} G_{r'x}^0 s_x &= g_1 = I_e^{SV} \cos i \sin i \\ G_{r'x}^0 s_z + G_{r'z}^0 s_x &= g_2 = I_e^{SV} (\cos^2 i - \sin^2 i) \\ G_{r'z}^0 s_z &= g_3 = -I_e^{SV} \sin i \cos i, \end{aligned} \quad (25)$$

and for qSH

$$\begin{aligned} G_{\varphi'x}^0 s_y + G_{\varphi'y}^0 s_x &= g_4 = I_e^{SH} \sin i \\ G_{\varphi'y}^0 s_z + G_{\varphi'z}^0 s_y &= g_5 = I_e^{SH} \cos i, \end{aligned}$$

where  $I_e^P$ ,  $I_e^{SV}$  and  $I_e^{SH}$  now define elementary wave mode phases (e.g. seismogram wavelets containing specific body wave phases) which consider the geometrical divergence, the attenuation and the travel time of the phase along the ray path between source and receiver. Note that  $G_{\varphi'x}^0 s_y = 0$  and  $G_{\varphi'z}^0 s_y = 0$  (see Dahm, 1996). Insertion in equation (14) leads to (see also Box 9.13 in Aki and Richards, 2002)

P wave:

$$\begin{bmatrix} u_{r'}^P \\ u_{z'}^P \end{bmatrix} = \begin{bmatrix} (I_e^P)_{r'} \\ (I_e^P)_{z'} \end{bmatrix} \star \left[ (M_{xx} \cos^2 \varphi + M_{yy} \sin^2 \varphi + M_{xy} \sin 2\phi) \sin^2 i \right. \\ \left. + (M_{xz} \cos \phi + M_{yz} \sin \phi) 2 \sin i \cos i \right. \\ \left. + M_{zz} \cos^2 i \right]$$

SV wave:

$$\begin{bmatrix} u_{r'}^{SV} \\ u_{z'}^{SV} \end{bmatrix} = \begin{bmatrix} (I_e^{SV})_{r'} \\ (I_e^{SV})_{z'} \end{bmatrix} \star \left[ (M_{xx} \cos^2 \varphi + M_{yy} \sin^2 \varphi + M_{xy} \sin 2\phi) \sin i \cos i \right. \\ \left. + (M_{xz} \cos \phi + M_{yz} \sin \phi) (\cos^2 i - \sin^2 i) \right. \\ \left. - M_{zz} \sin i \cos i \right] \quad (26)$$

SH wave:

$$u_{\varphi'}^{SH} = (I_e^{SH})_{\varphi'} \star \left[ \left( \frac{1}{2} (M_{yy} - M_{xx}) \sin 2\varphi + M_{xy} \cos 2\varphi \right) \sin i \right. \\ \left. + (M_{yz} \cos \varphi - M_{xz} \sin \varphi) \cos i \right]$$

Note that for each body wave phase of qP, qSV or qSH type only one elementary “phase-wavelet” enters the moment tensor representation. Equation (26) forms the basis for the well known polarity method, where for each phase only the polarity is considered to constrain the focal solution of a double couple source (see chapter 3). It is also the basis for a moment tensor inversion based on generalized rays (e.g. Nabelek, 1984), peak amplitude (e.g. Ebel and Bonjer, 1990), and amplitude ratios or the relative moment tensor inversion (e.g. Dahm, 1996).

Equation (26) can be used for body wave peak amplitude moment tensor inversion of weak and moderate events with short source duration. For instance, peak amplitudes or waveform moments (=displacements integrated over the first pulse) of low pass filtered P and S phases may be measured and used as input data for inversion. Low pass filtering with a passband below the corner frequency of the event has to be performed to avoid amplitude distortion from rupture directivity. Seismograms need to be deconvolved to ground motion to estimate true seismic moments. The geometrical ray parameters, i.e. the ray azimuth and take-off angle, are typically taken from a location program where ray tracing is performed. Although elementary seismograms  $I_e$  are reduced to a scalar factor comprising geometrical and intrinsic attenuation, and therefore might be estimated by ray tracers during location, it is recommended to extract  $I_e$  from complete synthetic seismograms which are filtered in the same way as the observed seismograms. This may avoid bias from apparent polarity flipping, a problem that may occur if short period stations were used. The method has been used occasionally for short period local and teleseismic earthquakes studies but is now of lesser relevance since broadband data are often available. Data problems were often difficult to identify since observed and synthetic waveforms were not directly compared. In order to further stabilize the method, pure double couple constraints (shear crack constraints) can be introduced.

A derivative of the peak amplitude method is the amplitude ratio method to determine focal solutions for double couple sources. Amplitude ratios between P, SV and SH phases are used as input data, together with P phase polarities, and the associated relations between the

elementary seismograms  $I_e$  of the different wave modes are considered from ray theory. A commonly used Fortran package is *focmec* (by A. Snoke, see <http://www.iris.edu/pub/programs/focmec>).

### 3.5 Relative moment tensor inversion using multiple events (body wave method)

To locate earthquakes multiple event inversions were developed. Well-known examples are the joint hypocenter, the master event location and the hypoDD methods (IS11.1). A moment tensor approach similar to the master event location was developed by e.g. Dahm (1996). The method is of interest if earthquake clusters are analyzed. Spatially clustered seismicity may occur for example during aftershock sequences, for earthquakes swarms in volcanic and geothermal areas, or at specific structures at tectonic faults or subducted plates (e.g., deep earthquake clusters). The concept of the relative moment tensor inversion is to use a reference mechanism (reference event) from the cluster, which is fixed during inversion, and to estimate the moment tensors of the studied events relative to the reference event. Since the studied and the reference earthquake from a tiny cluster have similar elementary seismograms  $I_e$ , the  $I_e$  factors can be eliminated from equation (26). Geometrical and intrinsic attenuation, amplification from site effects or unknown instrument functions have thus no or only a minor influence on the moment tensor result. The method is further described in Dahm (1996) and Dahm and Brandsdottir (1997). Necessary pre-requisites for application are that

- (a) the mechanism of the reference event is known a priori,
- (b) the events are tightly clustered and seismograms are low-pass filtered, so that events can be regarded as temporal and spatial point sources within approximately one wavelength from the reference event,
- (c) seismograms are low-pass filtered prior to measuring peak amplitudes. The corner frequency of the low-pass filter should be in the range of the corner frequency of the largest studied event of the cluster (potentially limiting the size of the smallest event that can be analyzed).

Dahm (1996) describes an extension of the method, for which the necessity of a fixed reference mechanism can be dropped when the radiation patterns within the earthquake cluster differ sufficiently.

### 3.6 Full waveform method using amplitude spectra

Full waveform methods considering broadband seismograms are nowadays routinely in use to study moderate and strong earthquakes at regional and teleseismic distances. As discussed in the previous paragraphs unconsidered phase shift between Green functions and data may be present if the centroid coordinates are incorrect or if the Earth model to calculate Green's functions is too simplified. Amplitude spectra inversions neglect the phase information. In the frequency domain, equation (15) can be written as

$$\tilde{d}(\omega) = \tilde{G}'_{nk}(\omega) y_k(\omega) = \left[ \text{Re}\{\tilde{G}'_{nk}\} + j\text{Im}\{\tilde{G}'_{nk}\} \right] y_k \quad , \quad (27)$$

where  $\text{Re}\{\}$  and  $\text{Im}\{\}$  are the real and imaginary part of the complex spectrum and  $j$  is the imaginary unit. The absolute value of the spectral seismogram amplitudes are then

$$|\tilde{d}| = \left[ \left( \text{Re}\{\tilde{G}'_{nk}\} y_k \right)^2 + \left( \text{Im}\{\tilde{G}'_{nk}\} y_k \right)^2 \right]^{1/2} = f(\tilde{G}', y) \quad . \quad (28)$$

The amplitude spectrum (28) is a non-linear function  $f$  of the moment tensor components  $y$ . The problem can be linearized and solved by an iterative inversion scheme (e.g., the gradient method). Equation (28) is linearized by means of the linear term of a Taylor's series expansion around a starting moment tensor solution. During each iteration, changes of moment tensor components are solved by minimizing the residual data vector. Local minima can be easily avoided if different starting models are considered by means of a grid search, e.g. represented by double couple starting solutions with different orientations. Examples are provided in e.g. Dahm et al. (1999 and Cesca et al. (2006).

Amplitude spectra inversion is in generally more robust and independent of phase misalignments as long as the time windows taken for inversion contain the phases modeled by Green's functions. The most serious drawback of amplitude spectra inversion is that the polarity of the source mechanism is not used resulting in a set of two indistinguishable moment tensor solutions with common nodal planes but different polarities. Therefore, amplitude spectra inversion is often implemented as a first step inversion, which is refined in a second step by considering additional constraints. For instance, polarity information of first onsets of body wave phases may be used to resolve the polarity ambiguity. A more elegant waveform approach is to use the results from the first inversion to estimate phase shifts at selected high quality stations, e.g. by means of cross correlation between observed and predicted waveforms, and to add these time domain traces in a second inversion step (e.g. Heimann, 2011; Cesca et al., 2010). The second step may either use time traces of phase corrected waveforms only or may be run as a weighted mixed input inversion considering amplitude spectra at all stations and time traces at selected key stations only. Since computation time and memory is not an issue any more we recommend the two-step inversion, which can easily be automated and reduces the problem of misaligned phases due to incorrect Earth models or earthquake locations.

### 3.7 Moment tensor representation using eigen-vibrations and eigen-modes of the Earth

The moment tensor representation calculates ground displacement as a sum of weighted Green functions (elementary seismograms), where weights are represented by moment tensor components. How the Green's functions are calculated is not specified. Most often, surface or body waves are used for moment tensor inversion. Body and surface waves in any finite body can be understood as a sum over a large number of eigenvibrations of this body. Therefore, Green's functions and synthetic seismograms may be calculated by summing up normal modes of the Earth. Such an approach was used by the first systematic global centroid moment tensor program led by A. Dziewonski in the early 1980's at Harvard University inverting fundamental modes and long period surface waves ( $> 135$  s). Other types of representation formulas may be derived for the normal mode theory, which are not further specified here (see, e.g., Dahlen and Tromp, 1998). Normal mode theory, for a long time, has been the most complete approach to calculate synthetic seismograms and Green's functions, since self gravitation, Earth rotation, Earth ellipticity and pre-stress are all included.

### 3.8 Codes to calculate Green functions for moment tensor inversion

Depending on the mode and type of selected data different computer codes can be recommended to calculate synthetic Green functions. The list below is incomplete and represents a selection based on the author's experience.

**Table 2** Computer codes to calculate synthetic seismograms

| Input data                                                                    | Type of code                                                                                                                                                           | Name of code          | Link, reference                                                                                                                                                                                                                                    |
|-------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Local and regional full waveforms (body and surface waves), high frequencies. | Reflectivity, layered Earth models, anisotropy & intrinsic attenuation, receiver at depth                                                                              | Qseis (fortran code)  | Wang (1999), <a href="ftp://ftp.gfz-potsdam.de/pub/home/turk/wang/qseis2006-code+input.zip">ftp://ftp.gfz-potsdam.de/pub/home/turk/wang/qseis2006-code+input.zip</a>                                                                               |
| Global and regional full waveforms                                            | Numerical integration of the SODE (integration of minors)                                                                                                              | GEMINI (fortran code) | Friederich and Dalkomo (1995), <a href="http://www.quest-itn.org/library/software/gemini-greens-function-of-the-earth-by-minor-integration">http://www.quest-itn.org/library/software/gemini-greens-function-of-the-earth-by-minor-integration</a> |

| Free oscillations, long period surface waves                                  | Numerical integration, layered Earth models, self gravitation, anisotropy, attenuation.                                                                                | MINEOS (fortran)      | <a href="http://www.geodynamics.org/ci/g/software/mineos">http://www.geodynamics.org/ci/g/software/mineos</a>                                                                                                                                      |
| Full waveforms                                                                | Numerical approach, 3D Earth models, ellipticity, rotation, self gravitation, attenuation.                                                                             | SPECFEM3D             | <a href="http://www.geodynamics.org/ci/g/software/specfem3d-globe">http://www.geodynamics.org/ci/g/software/specfem3d-globe</a>                                                                                                                    |

Green's function can be pre-calculated for specific Earth models (e.g. standard models) and stored in Green's function databases. They can then be shared over the internet, e.g. on the KINHERD web page (<http://kinherd.org>), from where they can be downloaded by users, for instance if computing power or facilities are not available to build own databases. Exercise EX 3.6 gives an example, referring to moment tensor inversion based on the Pyrocko package (<http://emolch.github.com/pyrocko>) or the Kiwi Tools (<http://kinherd.org/kiwitools>) (e.g. RAPIDINV, see <http://kinherd.org/rapidinv>), which can directly use these pre-calculated databases.

## 4 Moment tensor inversions schemes in practice

Solving equation 3 in the time or in the frequency domain includes several steps from data preparation and Green's function calculation to solving a system of linear equations. The reliability and evaluation of the outcome, i.e. a moment tensor, depends not only on the datasets and a formal error estimation but on many additional factors, where the most important are listed below.

### 1) Data acquisition and pre-processing

- selection of seismograms with good signal-to-noise ratio
- unclipped signals
- good azimuthal coverage
- removing mean value and linear trends, detection of data gaps
- correcting for instrument response, converting seismograms to displacement, velocity or acceleration
- selection of waveforms, e.g., P, S and surface wave windows or full seismograms
- low-pass filtering appropriate to the dataset to remove high-frequency noise and estimating the corner frequency of the source to safely satisfy the point source approximation

### 2) Calculation of accurate synthetic Green functions for specific

- earth model
- location of the source
- receiver position

### 3) Inversion and interpretation of the inversion result

- decision for an inversion algorithm to solve eq. 3 or eq. 12
- test of resolution for all free parameters of the source model
- decomposition of the moment tensor, e.g., into best double couple plus CLVD

The inversion may be performed in the time or frequency domain either using a singular value decomposition to calculate the generalized inverse matrix or, e.g., by LU decomposition. We do not provide details: the reader may find more information and software in Press et al. (2007) (chapter 2, especially 2.3). A general introduction and overview on data inversion can be found in the textbooks of Menke (1989) and Aster et al. (2013). Linearization and iterative solution strategies using one specific or a set of start models are required for instance to solve eq. 12 (amplitude spectra based solution).

Care must be taken to match the synthetic and observed seismograms. Alignment of observed and synthetic waveforms is facilitated by cross-correlation techniques. In most moment-tensor inversion schemes, focal depth is assumed to be constant. The inversion is done for a range of focal depths and the best solution is assumed to be the with the lowest misfit.

Dufumier and Cara (1995) and Dufumier (1996) give a systematic overview for the how  $M_{ij}$  results are affected by differences in the azimuthal coverage and by using only P waves, P plus SH waves or P and SH and SV waves for the inversion with body waves. Their results indicate the most important factor is good azimuthal coverage, followed by the combined use of P and S phases (and Love and Rayleigh waves). A systematic overview with respect to the effects caused by an erroneous velocity model for the Green function calculation and the

effects due to wrong hypocenter coordinates can be found in Šilený et al. (1992), Šilený and Pšenčík (1995), Šilený et al. (1996) and Kravanja et al. (1999).

The dynamical boundary conditions on the solid free surface imply that the moment tensor elements  $M_{xz}$  ( $= M_{13}$ ) and  $M_{yz}$  ( $= M_{23}$ ) vanish as the source location approaches the Earth's free surface or the seafloor. As a result, these vertical dip-slip components are not well constrained for shallow-focus sources. A discussion regarding the related uncertainties for the determination of focal mechanisms, the centroid depth but also the scalar seismic moment can be found in Bukchin et al. (2010).

Depending on the dataset the isotropic component,  $M_{iso}$ , may be difficult to resolve. Therefore, an isotropic component with strength of less than 10% of the strength of the full moment tensor is often considered to be insignificant. A better approach is to test the statistical significance, e.g. by means of an F-test.

Significant CLVD components are often reported for large intermediate-depth and very deep earthquakes. In many cases, however, it can be shown that these may be caused by the superposition of several sub-events with different double-couple mechanisms (Kuge and Kawakatsu, 1990; Frohlich, 1995; Tibi et al., 2001).

How good is a specific solution? Several standard approaches exist to get an answer to this question. The numerical stability of the inversion can, for instance, be checked with the condition number. This number is defined as the ratio between the square root of the largest eigenvalue to the smallest eigenvalue of the generalized inverse and is an outcome of calculating the generalized inverse using a singular value decomposition method. It indicates the overall sensitivity of the solution to errors in the data. For iterative inversion schemes straightforward error estimation techniques are not applicable. One way to estimate the errors in the solutions is the use of many start models within reasonable limits and subsequent evaluation of the scatter in the resulting model parameters. Jackknifing and bootstrapping (see, e.g., Shao and Tu, 1995) are also widely used methods to test the stability of solutions, especially when non-linear iterative schemes are used (e.g., Heimann, 2011; Zahradník and Custódio, 2012). See also Valentine and Trampert (2012) for a recent assessment of uncertainties for centroid moment tensor determinations.

## 5 Free software packages for moment tensor inversion

Here we list freely available software packages for moment tensor inversion. We mention briefly differences regarding the distance range and details of the inversion outcome.

- RAPIDINV (Cesca, 2010), based on the Kiwi Tools (Heimann, 2011): Time and frequency domain inversion code in the regional and teleseismic distance range using full waveform Green's function databases. Includes inversion for point source, simple finite sources and extensive resolution testing, see <http://kinherd.org/rapidinv> and exercise 3.6 of the NMSOP-2: „A practical in moment tensor inversion using the Kiwi tools“ (<http://gfzpublic.gfz-potsdam.de/pubman/item/escidoc:130023:6>)
- VOLPIS (Cesca and Dahm, 2007). A stand-alone frequency domain inversion code (fortran) for the study of time-dependent source parameters for long period volcanic

signals. Single forces and dipole forces (moment tensors) can both be inverted (<http://kinherd.org/volpis>).

- Time-Domain Moment Tensor INVerse Code (TDMT-INVC) by Dreger (2003), for a description and software download see [www.orfeus-eu.org/pub/software](http://www.orfeus-eu.org/pub/software)
- Regional moment tensor inversion code together with tutorial and examples by B. Herrmann see [www.eas.slu.edu/eqc/eqccps.html](http://www.eas.slu.edu/eqc/eqccps.html)
- ISOLA-GUI which is a matlab GUI for regional moment tensor inversion written by J.Zahradnik and E. Sokos, see <http://seismo.geology.upatras.gr/isola>
- mtinvers (Dahm et al., 2007) is a stand-alone fortran code for regional and teleseismic point source inversion. Inversion can be constrained to opening/closing cracks, double couple source, shear source (<http://kinherd.org/mtinvers>).
- Mtnv package written by C. Ammon and G. Randall for point source moment tensor inversion in time domain in the regional distance range, see <http://eqseis.geosc.psu.edu/~cammon>
- MT5 package (McCaffrey et al., 1991) is a PC based software package for the inversion of teleseismic body waves for moment tensor solutions or double couple fault plane solutions, see <http://ees2.geo.rpi.edu/rob/mt5> and can also be found in the IASPEI Software Library, number 4.

Differences between the available packages arise from the implementation of constraints in the inversion either to stabilize the solution or for special purposes. As was mentioned in the subsection on problematic sources and moment tensor decomposition it is for many problems desirable to constrain the moment tensor to its deviatoric part by setting the trace of the moment tensor equal to zero. In this case only 5 moment tensor elements are left and the corresponding linear equation system can be found by recombining terms in the Eqs.s (3) and (6,7). This problem is still a linear one. Other constraints used are: double couple, tensile crack or a mixed situation. In these cases the inversion becomes non-linear and iterative inversion schemes have to be used.

The offered codes differ in several aspects. In the teleseismic distance range differences arise mainly regarding the computation of full wavefield Greens functions and the use of complete seismograms and/or if the inversion is performed for specific body wave phases like P and S and if surface waves are included. Here again an important detail is if the flat Earth transformation (Chapman 1973; Müller, 1977; Bhattacharya, 1996) is used to account for the sphericity of the Earth or if full wavefield Green's functions are calculated directly for the spherical Earth or if normal modes are used (see chapter 2.5 for freely available codes for the computation of full wavefield Green's functions).

In the regional distance range more codes are available to calculate full wavefield synthetics for layered media. The use of a regionally valid velocity model is critical (e.g. Donner et al., 2013). It should be mentioned that many velocity models used for location may show problems when used to produce longperiod surface waveforms because they may have been tuned to fit the crustal and upper mantle P-wave velocities not the S-wave velocities in the uppermost crustal layers.

Some codes use a full grid search regarding centroid time, centroid location and centroid depth: most codes at least search for a best fitting centroid depth.

Exercise EX 3.6 of the NMSOP-2 (DOI: 10.2312/GFZ.NMSOP-2\_EX\_3.6) provides a tutorial on how to setup Green's function databases and the MT inversion by using the Kiwi Tools.

## 6 Moment tensor catalogues

In the late 1970s and early 1980s the group headed by A. Dziewonski at Harvard University began routine determination of the seismic source parameters of all earthquakes with magnitude  $\geq 5.5$  using the centroid moment tensor (CMT) method (Dziewonski et al., 1981). This inversion tries to fit simultaneously the very long-period body wave train from the P arrival until the onset of the fundamental modes and mantle waves with periods longer than 135 s using synthetics produced by normal mode summation (see chapter 2.6). In addition the best point-source parameters (centroid epicentral coordinates, centroid depth and origin time) and the six independent moment tensor elements were published.

The Harvard group maintained, from 1981 to 2006, an extensive catalog of centroid moment-tensor (CMT) solutions for strong (mainly  $M \geq 5.5$ ) earthquakes since 1976. This catalog is now maintained and continued by the Global Centroid Moment Tensor Project at Lamont-Doherty Earth Observatory (LDEO) of Columbia University. Their solutions, as well as quick CMT solutions of recent events, down to moment magnitudes  $M_W \approx 4.5$  can be viewed at <http://www.globalcmt.org>. The products are also distributed by IRIS (see <http://www.iris.edu/spud/momenttensor>) and other data centers like the USGS. Harvard CMT solutions for the very largest, gigantic earthquakes (e.g.,  $M_W$  9.3 Sumatra, 26 December 2004) turned out to be systematically deficient (Stein and Okal, 2005; Tsai et al., 2005), and provisions have now been made to use longer periods for mega earthquakes.

As mentioned above the CMT inversion procedure seeks a solution for the centroid location of the earthquake. This centroid location may, for very large earthquakes, significantly differ from the hypocenter location based on arrival times of the first P-wave onsets. This initial hypocenter location corresponds to the place where rupture started. Therefore, the offset of the centroid location relative to the hypocentral location gives a first indication on fault extent and rupture directivity. In the case of the August 17, 1999 Izmit (Turkey) earthquake the centroid was located about 50 km east of the P-wave hypocenter. The centroid location coincided with the area where the maximum surface ruptures were observed.

Several institutions publish in recent years moment tensors determined using the W-phase (Kanamori, 1993; Kanamori and Rivera, 2008; Duputel et al., 2012). The ultra-longperiod W phase follows direct P on very broadband seismograms. Its use has the advantage to provide correct spectral levels for scalar moment determination also for slow ruptures what is important due to their high tsunami potential. See [eost.u-strasbg.fr/wphase](http://eost.u-strasbg.fr/wphase) for a description of the method, the catalog and a list of further publications.

Several other institutions offer regularly moment tensor solutions. The following list is not complete and what is described may change in detail.

One of the most complete regional archives is published by Berkeley Seismological Laboratory (BSL) for Northern California based on inversion of full waveform synthetics mainly of mid- and longperiod surface waveforms (Dreger and Helmberger (1993) and Dreger (2003). The catalog reaches back till 1993. More references to methodological work and example cases can be found on the webpage [seismo.berkeley.edu/mt](http://seismo.berkeley.edu/mt).

Another regional catalog for Southern California is published by the Southern California Earthquake Data Center (SCEC) since 2000 and can be found at <http://www.data.scec.org>.

GEOAZUR-SCARDEC method. GEOAZUR offers near realtime moment tensor solutions for larger worldwide events using a body wave deconvolution method (Vallee et al., 2011).

An estimate for a point source source time function and plots showing the fit of synthetics and observed waveforms for P and SH are provided.

See <https://geoazur.oca.eu/spip.php?article1236>

GFZ worldwide moment tensor solutions are distributed since 2011. Solutions are based on a modification of the code of Dreger and Helmberger (1993) and Dreger (2003) and are given in text or graphical form. A catalogue can be found at <http://geofon.gfz-potsdam.de/eqinfo/list.php?mode=mt>

A fully automatic global moment tensor catalogue, since 2012, is provided by GFZ using the Kiwi Tools package. Uncertainties are evaluated using bootstrapping methods. Kinematic source solutions of the extended source are calculated for selected events (see Heimann, 2011). Catalogue can be found under <http://kinherd.org/quakes/>

The National Observatory of Athens (NOA) provides fast moment tensor solutions for events in the Mediterranean Sea region down to a magnitude of about Mw 3.5. The ISOLA software (Sokos and Zahradník, (2008, 2013). is used and a grid search to find the best centroid parameters is performed. Plots showing the fit of the synthetics to the waveforms are provided. See also

<http://bbnet.gein.noa.gr/HL/seismicity/moment-tensors>

INGV uses the Dreger (2003) time domain method to invert for moment tensors of earthquake in Italy and the surrounding regions. Solutions are provided in form of pdf files showing moment tensor solutions in text and graphical form. The quality of the solution can be judged from the fit of longperiod synthetic and data waveforms together with maps showing the azimuthal distribution of stations. See <http://cnt.rm.ingv.it/tdmt.html>

INGV Bologna provides a different catalog for earthquakes larger than Mw 4.0 for events in Italy and larger than Mw 4.5 for events in the wider region based on an adaption of the centroid moment tensor method to model mid-period surface waves (Pondrelli et al, 2006, 2011 ). Solutions since 1976 are provided in text and graphical form.

The SED/ETHZ provides an automatic regional moment tensor catalogue for the entire European-Mediterranean region. Until 2010 the method was based on Braunmiller et al. (2002) and Bernardi et al. (2004). The reviewed catalog covers 1999 to 2006, the automatic MT catalog 2002-2010 (see <http://www.seismo.ethz.ch/prod/tensors/index>). The current regional MT determination covers Switzerland and vicinity and is based on the Dreger code and is described in Clinton et al., 2006).

Regional moment tensor solutions for Spain and its surroundings are provided by IGN, see e.g. <http://www.ign.es/ign/layoutIn/sismoPrincipalTensorZonaAnio.do> Solutions are provided in text (Spanish language) and graphical form. A number for the variance reduction and waveform fits are provided.

The USGS provides several types of moment tensor solutions. The „fast“ moment tensor solutions are based on body wave inversion only. The USGS centroid moment tensors are resulting from longperiod full waveform inversion. Additionally the USGS publishes W-phase moment tensors from inversion of the ultra-longperiod W phase following direct P on very broadband seismograms. The latter has the advantage to provide correct spectral levels

for scalar moment determination also for slow ruptures important due to their tsunami potential. See the USGS homepage (in the moment under reconstruction)

An interesting approach using a systematic grid search over possible time and spatial centroid positions in the regional distance range and subsequent moment tensor inversion on longperiod time domain waveforms is used by H. Kawakatsu (ERI Tokyo University) and is published on [http://www.eri.u-tokyo.ac.jp/GriD\\_MT/](http://www.eri.u-tokyo.ac.jp/GriD_MT/).

The following table summarizes specific aspects of the published catalogs.

**Table 3** list of published moment tensor catalogs

| Service   | Range                                                  | Data, bandwidth                                                                                                                                                                                                                                                | Greens functions          | Constraints | Additional parameter       | Error bounds                                          | Inversion type         |

## 7 Acknowledgments

Many students, course participants and colleagues helped improving the material over the years. We thank Peter Bormann for his persistent requests and reminders to deliver and improve the information sheets. We acknowledge the suggestions for improvement and careful reviews of Jochen Braunmiller, Daniela Kühn, Peter Bormann and Stefanie Donner.

| Contributor | James Dewey, U. S. Geological Survey/NEIC, MS 966, Denver, CO 80225-0046; E-mail: <a href="mailto:jdewey@usgs.gov">jdewey@usgs.gov</a> |
| Versions    | November 2011; DOI: 10.2312/GFZ.NMSOP-2_PD_3.1                                                                                         |

The following FORTRAN program, *pdemagcomp.f*, is based on a code for computing *mb* magnitude in the PDE bulletin of the USGS/NEIC. The original author is unknown. The program incorporates a procedure, *mbmag*, that has been used for decades to compute *mb* magnitude for the USGS/NEIC. It is included to provide the source code for *mbmag* and to show how *mbmag* is used. Program *pdemagcomp.f* was written by James W. Dewey, USGS/NEIC, for a limited research objective.

### **pdemagcomp.f.**

- c program pdemagcomp.f
- c calculates a Gutenberg-Richter *mb*, given epicentral distance,
- c event focal depth, amplitude in nanometers and period in seconds
- c requires 'qfile', the table of Gutenberg-Richter Q values

```
common q(108,17)
character*1 mbflg
real mb
```

```
open(unit = 23, status = 'old', file = 'qfile')
read (23,32,end = 33) ((q(i,j),j=1,17),i=1,108)
32 format(17(x,f4.2))
33 continue
```

```
type *, 'enter event focal depth, f5.1'
read *, depth
type *, 'enter station epicentral distance, degrees, f6.2'
read *, delta
type *, 'enter amplitude in nanometers, f7.1'
read *, amp
type *, 'enter period in seconds, f3,1'
read *, t
type *, 'enter P-wave travel-time residual in seconds, f5.1'
read *, res
call mbmag(t,amp,mbflg,mb,depth,delta,res)
type *, 'mb = ', mb, 'mbflag = ', mbflg
stop
end
```

```
subroutine mbmag(t,amp,mbflg,mb,depth,delta,res)
```

- c explanation of parameters (J. Dewey, 3/31/99)
- c t = P-wave period
- c amp = amplitude in nanometers
- c mbflg = 'n' -- computed magnitude not reported for this station
- c = 'R' or 'r' -- computed magnitude reported for this station,
- c but not used to compute average event magnitude
- c mb = short-period P-wave magnitude
- c depth = focal depth in km
- c delta = epicentral distance in degrees

```

c  q = magnitude calibration function for Gutenberg-Richter mb.  tabulated
c    from 2 to 109 degrees, at depths of 0,25,50,75,100,150,...,650,700 km.
c  res = travel-time residual, in seconds, of P-wave with which
c    this magnitude is associated

      common q(108,17)
      character*1 mbflg
      real mb

c
      11 mbflg='n'
      return
      end
=

```

The following Q-table is used at the USGS/NEIC to compute the short-period body-wave magnitude *mb* that is published in the PDE bulletin of the USGS/NEIC. For distances from 5° to 109°, it represents a "digitized" version of Figure 5 of B. Gutenberg and C.F. Richter, 1956, "Magnitude and Energy of Earthquakes", *Annali di Geofisica*, v. IX, n. 1, p. 1-15. The original figure is reproduced as Figure VIII-6 in Richter, C.F., 1958, *Elementary Seismology*, Freeman, San Francisco, 768 p. The origin of the Q values at distance less than 5° is not documented. The USGS/NEIC does not compute *mb* for all distance ranges represented in the table.

## 4.1 Introduction

### 4.1.1 About this chapter

Seismic signals are usually transient waveforms radiated from a localized natural or man-made seismic source. They can be used to locate the source, to analyze source processes, and to study the structure of the medium of propagation. In contrast, the term “seismic noise” designates undesired components of ground motion that do not fit in our conceptual model of the signal under investigation. What we identify and treat as seismic noise depends on the available data, on the aim of our study and on the method of analysis. Accordingly, data treated as noise in one context may be considered as useful signals in other applications. For example, short-period seismic noise can be used for microzonation studies in urban areas (see Chapter 14), and long-period noise for surface-wave tomography (Yanovskaya, 2012).

Although seismic noise proper relates only to the first four bullet point below disturbing noise in seismic records may in a wider sense comprise the following:

- Ambient vibrations due to natural sources (like ocean microseisms, wind, etc);
- Man-made vibrations (from industry, traffic, etc);
- Secondary signals resulting from wave propagation in an inhomogeneous medium (scattering);
- Effects of gravity (like Newtonian attraction of atmosphere, horizontal accelerations due to surface tilt);
- Signals resulting from the sensitivity of seismometers to ambient conditions (like temperature, air pressure, magnetic field, etc);
- Signals due to technical imperfections or deterioration of the sensor (corrosion, leakage currents, defective semiconductors, etc);
- Intrinsic self-noise of the seismograph (like Brownian noise, electronic and quantization noise);
- Artifacts from data processing.

The study of earthquakes or the imaging of the Earth with seismic wave arrivals requires their detection above background noise in seismic records. Levels of natural ambient noise may vary by 60 dB (a factor of 1000 in amplitude) depending on location, season, time of day, and weather conditions (see Fig. 4.30). This corresponds to differences in detection thresholds for seismic arrivals by about three magnitude units. Therefore, prior investigation of noise levels at potential recording sites is of utmost importance.

In the following we will look into

- different mathematical representations of seismic noise and signals;
- origins of natural and man-made ambient seismic noise;
- basic features of signals and noise in the wide frequency range of interest, from local micro-earthquake to normal mode recordings ( $0.2 \text{ mHz} < f < 100 \text{ Hz}$ );
- influence of sensor-recorder-filter responses and of the installation environment on the appearance of signals and noise in seismic recordings;
- task-dependent procedures for SNR improvement of earthquake and explosion records;
- global detectability thresholds for short-period and long-period signals.

For an overview of procedures that emphasize on the causes and treatment of noise in seismic exploration we refer to Kumar and Ahmed (2011).

#### 4.1.2 Nature and mathematical representation of signals and noise

As illustrated in Fig. 1.1, one of the key problems in seismology is to solve the inverse problem, i.e., to derive from the analysis of seismic records information on the structure and physical properties of the Earth through which the seismic waves propagate (see Chapter 2), as well as on the geometry, kinematics and dynamics of the seismic source process (see Chapter 3). The study of source processes is complicated by the fact that the seismic signals are weakened and distorted by geometric spreading and attenuation and due to reflection, diffraction, mode conversion and interference during their travel through the Earth. They are also distorted by the seismograph. While the Earth acts as a low-pass filter by attenuating higher frequencies most effectively, a mechanical seismograph is a second-order high-pass filter with a roll-off of  $-12 \text{ dB}$  (a factor of 4) per octave for periods larger than its eigenperiod (see Chapter 5).

Additionally, seismograms contain noise and the desired signals are sometimes completely masked by it. Therefore, one of the main issues in applied seismology is to ensure a good signal-to-noise ratio (SNR) both by selecting recording sites with low ambient noise and by data processing. The success of the latter largely depends on our understanding of the ways in which seismic signals and noise differ. The basic mathematical tool for this purpose is the harmonic or Fourier analysis, that is, the decomposition of a signal into sinewaves. Depending on the type of signal (transient or stationary, continuous or sampled) different mathematical formulations must be used.

The Fourier integral transformation (section 4.2.1) can only be applied to transient signals (signals that disappear or decay after some time so that they have a finite energy). For other signals, the integral may diverge. The discrete transformation (section 4.2.2) requires a sam-

pled signal of finite duration. Signals whose (mean) amplitude does not vary much within the interval of time over which we typically analyze earthquake signals are mathematically treated as stationary signals, that is, signals whose statistical properties do not change with time. Such signals require a different mathematical treatment. Of course, this is a mathematical idealization whose appropriateness depends on the time scale. Over longer intervals of time, almost all signals will change their statistical properties. For example, marine microseisms can normally be treated as stationary within the time frame of a seismogram but often change their amplitude and predominant period within a few days according to meteorological conditions over the oceans.

A Fourier transformation in the strict sense does not exist for stationary signals. This is not a practical problem because we can Fourier analyze such signals over finite time intervals of any desired length. A practically more important difference is that we are normally not interested in the detailed waveform of such signals because we want to remove them from the record, not to interpret them. (There are, however, interesting exceptions as mentioned in the introduction.) In most cases we only want to know how strong they are in different parts of the frequency spectrum. This information is contained in a quantity named **Power Spectral Density** that is explained in section 4.2.3.

Transient signals such as earthquake seismograms may have a complicated waveform, but this waveform is determined by the earthquake source, the structure of the Earth, and the properties of the seismograph. The amplitudes and phases of the harmonic components of the signal are not random numbers but follow certain mathematical relationships. They are, in principle, smooth functions of frequency, often smoother and simpler than the signal appears in time domain. For example, the waveform of a train of surface waves is essentially determined by a much simpler dispersion curve. Such waveforms or spectra are sometimes called deterministic, in contrast to the “stochastic” or “random” waveform of seismic noise. Strictly speaking, however, seismic noise is also deterministic. The difference is that we don’t know its sources and propagation paths well enough to predict or interpret the waveform, don’t want to care about them, and therefore assume that the spectral amplitudes and phases are random numbers. Again, this is a mathematical simplification that may or may not be appropriate.

## 4.2 Different mathematical formulations of spectral analysis

### 4.2.1 Fourier transformation of continuous transient signals

The signal radiated from a seismic source, be it an explosion or a shear rupture, is usually a more or less complicated displacement step function or velocity impulse of finite duration from milliseconds up to a few minutes at the most (see Chapter 2, Fig. 2.5 and Chapter 3, Figs. 3.4 and 3.9). According to the **Fourier theorem** any arbitrary **transient function**  $f(t)$  in the *time domain* can be represented by an equivalent function  $F(\omega)$  in the **frequency domain**. The mathematical relationship between the two domains is defined by the **Fourier integral transformation**:

$$(4.1) \quad f(t) = (2\pi)^{-1} \int_{-\infty}^{\infty} F(\omega) \exp(i\omega t) d\omega$$

$$(4.2) \quad F(\omega) = |F(\omega)| \exp(i\phi(\omega)) = \int_{-\infty}^{\infty} f(t) \exp(-i\omega t) dt$$

Other sign conventions may be used, e.g.  $\exp(-i\omega t)$  in Eq. (4.1) and  $\exp(i\omega t)$  in Eq. (4.2) in wave propagation studies in order to assure that the wave-number vector is positive in the direction of wave propagation. The normalization factor  $(2\pi)^{-1}$  may be applied in the backward or in the forward transformation, or its square root in both.  $f(t)$  needs not be a continuous function in a mathematical sense but it must be defined at every instant of time, with the possible exception of isolated points where a step may occur.

$F(\omega)$  is the **complex Fourier transform** of the continuous signal  $f(t)$ , usually written as a function of the angular frequency  $\omega$  which is  $2\pi$  times the common frequency (the number of cycles per second). The absolute value of the Fourier transform,  $|F(\omega)|$ , is called the **amplitude spectrum**, and its phase  $\phi(\omega)$  the **phase spectrum**. Fig. 4.1 gives an example. The phase may practically be measured in radians, cycles ( $2\pi$  radians), or degrees, although only radians are used in mathematical formulas. Since the integral in Eq. (4.1) is equivalent to a sum, the Fourier transformation implies that an arbitrary transient signal, even an impulsive one, can be represented as a sum of time-harmonic functions (sinewaves). Fig. 4.2 illustrates how a sum of harmonic terms can equal an arbitrary function.

**Fig. 4.1** A signal recorded as a function of time (left) can be represented equivalently in the frequency domain by its complex Fourier spectrum. The amplitude (middle) and phase spectrum (right) are both needed to calculate the complete time series (reproduced from Lay and Wallace, 1995, Figure 5.B1.1, p. 176; with permission of Elsevier Science, USA).

The concept of frequency filtering (for example, high-, low- or band-pass filtration) has its roots in analog signal processing and is therefore intimately connected to the Fourier Integral Transformation while practical procedures on a computer do not use integrals and are often only approximations to the corresponding analog procedures. Frequency filtering reduces the amplitudes of harmonic components of a signal in part of the frequency spectrum, usually in order to suppress noise. Examples will be given in paragraph 4.7.1 below. Filtering may also modify the phases. It will, in general, change the amplitude of the desired signal in time domain. Therefore, magnitudes of seismic events determined from amplitude and period readings of seismic phases are comparable only when determined from analog seismic records with identical standard frequency responses or digital records filtered accordingly (see IASPEI standards for magnitude measurement in IS 3.3). Systematic differences between various magnitude scales as well as saturation effects are the consequence of filtering the input signals with different responses in

different and often band-limited frequency ranges (see Chapter 3, Tab. 3.1 and Figs. 3.5, 3.20 and 3.47).

#### 4.2.2 Fourier transformation of sampled signals

A mathematically simpler and more computer-adequate formulation of the harmonic analysis is the *Discrete Fourier Transformation*:

$$(4.3) \quad a_k = \frac{1}{M} \sum_{l=-M/2}^{M/2-1} c_l e^{2\pi j k l / M}$$

$$(4.4) \quad c_l = \sum_{k=0}^{M-1} a_k e^{-2\pi j k l / M}$$

where  $a_k$  is a *time series* (a series of equidistant samples of a continuous signal  $f(t)$ ) and  $c_l$  are complex *Fourier coefficients*, each of which can again be decomposed into an amplitude and a phase factor. The index  $l$  represents the frequency. To obtain the frequency in physical units we replace  $k/M$  in the exponent by  $k\Delta t/M\Delta t$  where  $\Delta t$  is the sampling interval. Then  $k\Delta t$  is the time of sample  $a_k$  and  $l/M\Delta t$  is the frequency of the phase factor after  $c_l$ .  $T = M\Delta t$  is the length of the signal in time. Both series,  $a_k$  and  $c_l$ , are periodic outside their original interval of definition. So other conventions with respect to the index ranges of the summation are possible; all sums over  $M$  consecutive samples are equivalent. Supplementary information on different aspects of the Fourier transformation is found in Chapter 5, section 5.2.3 ff.

**Fig. 4.2** The transient signal is formed by summing up the harmonic terms of Eq. (4.3), a discretized version of Eq.(4.1). The amplitudes of each harmonic term vary, being prescribed by the amplitude spectrum  $|c_l|$ . The shift of the phase of each harmonic term is given by the phase spectrum (reproduced from Lay and Wallace, 1995, Figure 5.B1.2, p. 177; with permission of Elsevier Science, USA).

#### 4.2.3 Spectral analysis of stationary signals (noise)

As we have already said above, in the analysis of stationary noise we are normally not interested in the exact waveform or other details that do not convey useful information. In most cases, we only want to know “how strong” the noise is, or whether it will prevent us from detecting a specific earthquake signal. Since with frequency filters we may be able to sup-

press noise in one part of the spectrum and still preserve signals in another part, it is necessary to consider the spectral distribution rather than the total strength of both signals. There lies, however, a mathematical difficulty in this seemingly simple task: the formal measures of “strength” for transient and stationary signals are incompatible and cannot easily be compared. Mathematically speaking, transient signals have a finite energy and zero power (in the average over all times) while stationary signals have an infinite energy but a finite power. The same holds for the spectral densities. For a quantification of stationary noise, the concept of **Power Spectral Density (PSD)** is therefore appropriate while transient signals are more adequately described by their **Energy Spectral Density (ESD)**. The relationship between the two densities is trivial; we must however go into some mathematical detail to explain how they are calculated and used. In some situations (such as for the comparison of earthquake signals with instrumental clip levels) neither the PSD nor the ESD are suitable measures, and we must use other criteria which will be the subject of section 4.4.

Generally, the spectral density  $P(\omega)$  of some quantity  $Q$  is a function of frequency whose integral over a given frequency band (such as the passband of a specific seismograph) gives the total amount of  $Q$  in that band. When  $Q$  is the power of a signal, the physical dimension of  $P$  is power per bandwidth (per Hertz). However, not every quantity that has the physical dimension X per Hertz is a spectral density. For example, the Fourier transform  $F(\omega)$  in eq. (4.2) has the dimension  $\mu\text{m}$  per Hz when the seismic signal  $f(t)$  is measured in  $\mu\text{m}$ , but its absolute value  $|F(\omega)|$  is not an “amplitude spectral density” even if this name has been used by some authors (including Aki and Richards in their well-known textbook, 1980). Integrating  $|F(\omega)|$  over a bandwidth does, in general, NOT yield the amplitude of  $f(t)$  in that bandwidth, as demonstrated in Fig. 4.6.

#### 4.2.3.1 Energy and power densities of continuous signals

We can now explain how the Spectral Densities of Energy and Power are actually determined for a given signal. Mathematically we must distinguish between transient and stationary signals, and between continuous and sampled signals. Practically, of course, we always analyze signals of finite length that are, mathematically speaking, transient, and for digital processing the signals must be sampled. Still, most concepts behind data processing (such as using a sine-wave to represent a single frequency) come from the realm of continuous signals, and we must therefore start from the Fourier Integral Transformation even if it is not a practical tool for digital processing.

The Fourier Integral Transformation as formulated in Eqs. (4.1) and (4.2) has the mathematical property (known as Rayleigh’s or Parseval’s theorem)

$$(4.5) \quad \int_{-\infty}^{\infty} f(t)^2 dt = \int_{-\infty}^{\infty} \frac{|F(\omega)|^2}{2\pi} d\omega = \int_{-\infty}^{\infty} |F(2\pi\nu)|^2 d\nu$$

On the left side, we have what in data processing is called the total energy of signal  $f(t)$  (this is not a physical energy but proportional to it). We have assumed that the energy is finite even if the signal may mathematically have an infinite length (for example, it may decay exponentially). The right side then represents the energy as an integral of  $E = |F(2\pi\nu)|^2$  over all fre-

quencies  $\nu$ . Thus, according to the above definition, the integrand  $E$  is the Energy Spectral Density of the signal.

Note that negative frequencies must be included in the integration. For real signals, the ESD is a symmetric function,  $E(-2\pi\nu) = E(2\pi\nu)$ , so we can as well double it and integrate only over positive angular frequencies. This convention is normally used in engineering and other practical applications; the ESD is then given as twice the “mathematical” value. The same applies to the PSD in the next paragraph. It is important to clarify which convention is being used.

Power is energy per time. Normally we are not interested in the instantaneous power but in the average power over at least one cycle of the signal (if it is approximately periodic). The concept of power is mainly applied to stationary signals such as sinewaves or seismic noise whose average power is constant or varies slowly. A Fourier transform in a strict sense is not defined for such signals, but we can Fourier analyze the signal over any finite time interval of length  $T$ . When both sides of Eq. (4.5) are divided by  $T$ , the left side represents the average power, and  $P = E/T = F(2\pi\nu)|^2/T$  on the right side is the Power Spectral Density for that interval.

#### 4.2.3.2 Energy and power densities of sampled signals

We now consider a signal represented by  $M$  samples taken at equidistant intervals  $\Delta t = T/M$  where  $T$  is the total duration of the signal. The power  $W$  of such a signal is defined as the average square of the samples:

$$(4.6) \quad W = M^{-1} \sum a_k^2$$

Again, this is not a physical power, but the latter is proportional to  $W$ . The square root of  $W$  is the *effective* or *root-mean-square (rms) amplitude*  $a_{rms}$  of the signal. Now it is a property of the discrete Fourier transformation Eqs. (4.3) and (4.4) that

$$(4.7) \quad \sum a_k^2 = M^{-1} \sum |c_l|^2$$

Like in the case of Eq. (4.5), the total power  $W = M^{-1} \sum a_k^2 = M^{-2} \sum |c_l|^2$  is now expressed as a sum of contributions from different frequencies. Only discrete frequencies  $l/T$  are used in the transformation, but if we go back to the domain of continuous signals and consider the Fourier coefficients  $c_l$  as samples of a continuous function, then each coefficient stands for a frequency interval of width  $1/T$  (this is sometimes called a “frequency bin”). The ratio of power over bandwidth at frequency  $l/T$  is therefore

$$(4.8) \quad P_l = M^{-2} T |c_l|^2 = M^{-1} \Delta t |c_l|^2$$

The series  $P_l$  is the discrete equivalent of the PSD function. It offers a practical way to compute the PSD for stationary signals. For a graphical representation, the  $P_l$  series is often smoothed and

decimated because the original coefficients are normally positive random numbers. The suitably smoothed PSD approaches, at each frequency, a definite limit for  $M \rightarrow \infty$  when the signal is stationary (this is essentially the definition of stationarity). For (supposedly) stationary signals like seismic background noise, calculating the PSD of a long but finite section is the only possible form of a spectral analysis. The PSD is not equivalent to a Fourier transform; the signal cannot be reconstructed from it with an inverse transformation because the phase information is lost. For finite sections of a stationary signal we can of course use the discrete Fourier transformation if we later need a backward transformation. The smoothed and decimated PSD is however normally more useful because it contains all essential information in a concentrated form, and eliminates arbitrary normalization factors. The discrete equivalent of the Energy Spectral Density is obtained as  $E_l = T \cdot P_l$ .

#### 4.2.3.3 Obtaining the ESD or PSD by spectral analysis of the autocorrelation

An alternative way of determining the spectral density of energy or power is to calculate the Fourier transformation of its autocorrelation. An autocorrelation can be defined for stationary signals that have no Fourier transform; the signal is then essentially defined via its autocorrelation, and needs not be explicitly known. The autocorrelation of a stationary signal  $f(t)$  is the expectation value of the product  $f(t) f(t + \tau)$ , often written as  $\langle f(t) f(t + \tau) \rangle$ . It is a function of the delay (or time lag)  $\tau$  and normally decays rapidly for large time lags. So one can truncate it without committing a large error and then Fourier transform it. The method can as well be applied to finite sections of a signal. The properly normalized Fourier transform is the PSD of the signal. For details, see Havskov and Alguacil, 2002. Truncating the autocorrelation also has the desirable effect of smoothing the PSD. Nevertheless the method is now obsolete as a practical tool; it dates back to the time when the Fast Fourier Transformation was not available, and relatively short truncated series were more convenient to transform.

#### 4.2.3.4 Testing PSD and ESD computation

Although the PSD and ESD of a given signal are in principle independent of the method of computation and of the normalization of the Fourier transform, there often remains an uncertainty whether a given formula or computer program delivers properly normalized values. The question is easy to settle. All that must be done is to analyze an arbitrary signal, calculate its power or energy in time domain, and check if the integral of the PSD or ESD over all (or over positive) frequencies reproduces it.

#### 4.2.3.5 Changing between displacement, velocity, and acceleration

By differentiating under the integral in 4.1, we see that the time-derivative  $\dot{f}(t)$  of a signal  $f(t)$  has the Fourier transform  $j\omega F(\omega)$ . So if the signal was originally measured as a displacement and we need the Fourier transform of the velocity, we obtain it by multiplying the original Fourier transform by  $j\omega = j \cdot 2\pi\nu$  where  $\nu$  is the common frequency. The Fourier transform of the acceleration is  $-\omega^2 F(\omega)$ . We can of course also go back from acceleration or velocity to displacement by dividing by the appropriate factor. The ESD and PSD are positive quadratic functions of the Fourier amplitudes, so differentiating the signal brings a factor  $\omega^2$ , integration a factor  $\omega^{-2}$ , etc. A PSD of velocity can thus easily be converted into that of displacement or acceleration. It has become a standard to measure seismic noise as a PSD of acceleration, that is,

in  $(\text{m/s}^2)^2$  per Hz or  $\text{m}^2\text{s}^{-3}$ . We note again that “power” in this context is not the physical power in watts but simply the mean square amplitude of ground acceleration.

#### 4.2.3.6 Representing PSDs in decibels

As in acoustics, the power ratio  $r = (a_2/a_1)^2$  between two signals of amplitude  $a_1$  and  $a_2$  is often expressed in Decibels (dB). This is a logarithmic measure that expresses a ratio as a difference of logarithms. The difference in dB is  $10 \log_{10}[(a_2/a_1)^2] = 20 \log_{10}[(a_2/a_1)]$ . When expressing the power spectral density  $P_a$  of acceleration relative to the metric unit  $1 (\text{m/s}^2)^2/\text{Hz}$ , we get

$$(4.9) \quad \mathbf{P_a[dB]} = 10 \log_{10} [P_a / 1 (\text{m/s}^2)^2/\text{Hz}]$$

For the rest of this paragraph, we must caution the reader that **numerical values of physically incommensurable quantities will be compared**. Equations (4.10) and (4.11) and the following two text lines do not imply that the decibel units on both sides of the equal sign mean the same. They only look the same because the incommensurable reference levels were omitted, not, however, in Figure 4.3, where the three different power units for  $P_a$ ,  $P_v$  and  $P_d$  have been given on the ordinate. This clarification notwithstanding one gets by substituting the period  $T = 1/f$  (in s) for the frequency  $f$  in (4.6) and (4.7) :

$$(4.10) \quad \mathbf{P_v[dB]} = \mathbf{P_a[dB]} + 20 \log (T/2\pi)$$

and

$$(4.11) \quad \mathbf{P_d[dB]} = \mathbf{P_a[dB]} + 40 \log_{10} (T/2\pi) = \mathbf{P_v[dB]} + 20 \log (T/2\pi)$$

Consequently, for the period  $T = 2\pi = 6.28$  s  $\mathbf{P_a} = \mathbf{P_v} = \mathbf{P_d}$  (only the numbers are equal!) Also,  $(\mathbf{P_d} - \mathbf{P_a}) = 2 \times (\mathbf{P_v} - \mathbf{P_a}) = \text{constant}$  for any given period, negative for  $T < 2\pi$  s and positive for  $T > 2\pi$  s (Fig. 4.3).

#### 4.2.4 Cross-correlation and coherence

The **cross-correlation** of two stationary signals  $f(t)$  and  $g(t)$  at the time lag  $\tau$  is defined as the expectation value (practically, mean value) of the product  $f(t) g(t + \tau)$ . Properly normalized, it is a measure of the similarity between the two signals and is called their **coherence** (consult a textbook on data processing for details). Like the Power Spectral Density, it can be calculated via the Fourier transformation and specified as a function of frequency, in which case the name **coherence spectrum** is more adequate (but not always used). Each signal is fully coherent with itself (the coherence equals 1); independent random signals are incoherent (their coherence equals zero) although strictly this is only true in the limit of an infinite duration and after removing the mean. More interesting is the case that signals are partially coherent. One can then conclude that with some (frequency-dependent) fraction of the power, a common signal is hidden in them, for example a seismic signal masked by instrumental noise of the sensors.

Seismic signals depend not only on time but also on the location where they are recorded. It is therefore meaningful to ask whether the signal recorded at one location is coherent with the same signal recorded at another location. This aspect of coherence is usually expressed as a “coherence

length” over which the recorded signals have a specified coherence. The coherence length is only a fraction of a wavelength for omnidirectional noise (noise propagating in all directions) but can be much longer when noise originates in a limited source area and propagates essentially in one direction (Fig. 4.22). In a plane wave, the coherence length is theoretically infinite.

## 4.2.5 The uncertainty principle of the Fourier Transformation

The time signal  $f(t)$  and its Fourier transform  $F(\omega)$  according to eq. (4.2) are related to each other through many rules that can be found in the textbooks (a few textbooks are named at the beginning of section 5.2). One such relationship, the uncertainty principle, is important for the following discussions. It states that an impulsive signal (one whose energy is concentrated in a short interval of time) must have a large bandwidth; a signal with a small bandwidth cannot be concentrated in time, or have a sharp onset. For any signal, the product of its width (uncertainty, variance) in time and its bandwidth (in terms of angular frequency) cannot be smaller than  $\frac{1}{2}$ . Only a Gaussian pulse (one with the envelope  $\exp(-\alpha t^2)$ ) gives the minimum value. Many figures in this chapter, starting from Fig. 4.6, are illustrations of the uncertainty principle. In quantum mechanics, the same mathematical relationship has the consequence that the position and momentum of a particle cannot be known at the same time; if the particle is sharply localized, then its momentum is uncertain and vice versa.

## 4.3 A first look at seismic and instrumental noise

### 4.3.1 Global models for the PSD of seismic noise

Fig. 4.3 is a summary of noise levels observed in a worldwide network of seismic stations (Peterson 1993). The graph shows the upper and lower envelopes (solid lines) of a large collection of curves representing the PSD of ground acceleration. The “engineering” convention is used, that is, the PSD has to be integrated over positive frequencies only. The envelopes are commonly referred to as the New High Noise Model (NHNM) and New Low Noise Model (NLNM). For periods which define the corners of the NLNM and NHNM polygons, Tables 4.1 and 4.2 give the displacement, velocity and acceleration power densities both in their respective kinematic units and in dB. A slightly different model was worked out by Berger et al. (2004) and is known as the GSN low-noise model. Fig. 4.3 also shows the lower envelopes for the PSDs of displacement and velocity. Displacements vary enormously between the short-period and the long-period end of the seismic spectrum. For the NLNM alone the variation is 260 dB (equivalent to 13 orders of magnitude in the signal amplitude) in the period range of seismological interest. The variation is reduced to about 130 dB for velocity and to 50 dB for acceleration. Understandably the PSD of acceleration is preferred for graphic representations. The noise peak of ocean microseisms around 5 s period (see 4.3.1) stands out most clearly here, as does the minimum near 0.04 Hz, termed “a window for earthquakes” by Savino et al. (1972). The height of the microseismic peak exhibits a strong seasonal variation. Another important minimum in the vertical-component seismic noise exists around 3 mHz which is important for free oscillation observations. The physical reasons for its existence have been discussed by Zürn and Wielandt (2007).

The ocean microseisms separate the two traditional domains of short-period ( $T < 2\text{--}3$  s) and long-period seismology ( $T > 10$  s). Broadband recordings spanning over this peak were rare after WWII, especially in the western world after the introduction of the US World-Wide Standard Seismograph Network (WWSSN). But even nowadays, with digital broadband-velocity

recording being the standard almost everywhere, it is usually necessary to filter data into the two bands above or below this peak to clearly detect seismic phase arrivals above the noise.

**Fig. 4.3** Envelope curves of acceleration noise power spectral density  $P_a$  (in units of dB related to  $1 \text{ (m/s}^2\text{)}^2/\text{Hz}$ ) as a function of noise period (according to Peterson, 1993). They define the new global high (NHNM) and low noise models (NLNM) which are currently the accepted standard curves for generally expected limits of seismic noise. Exceptional noise may exceed these limits. For the NLNM the related curves calculated for the displacement and velocity power spectral density  $P_d$  and  $P_v$  in units of dB with respect to  $1 \text{ (m/s}^2\text{)}^2/\text{Hz}$  and  $1 \text{ m}^2/\text{Hz}$  are given as well. Modified version of Figure 2 from P. Bormann, 1998 © Springer; with kind permission from Springer Science+Business Media.

It is often desirable to plot many PSD curves into one graph – for example, PSDs from all stations of a large network at the same time, or from many hourly or daily records of a single station. In that case, certain areas of a graph like Fig. 4.3 may become completely black, and it may be impossible to distinguish or label individual curves. A better way is then not to plot individual PSD curves but to represent the **probability density function or PDF** of the ensemble of PSD curves. (The PDF is unrelated to the .pdf format for electronic documents.) The PDF measures the relative density of PSD values (how many of the observed values lie in a small area of the graph) and is encoded with a color scale (Figure 4.4). PDF software is part of software packages like PQLX (<http://earthquake.usgs.gov/research/software/pqlx.php>; USGS Open-File Report 10-1292) or SEISCOMP3 (<http://www.seiscomp3.org/>). In interactive versions, the user can click into the plot area and obtain a listing of those seismic records

that have PSDs with the selected combination of frequency and PSD level. This can help to identify the cause of elevated noise levels, such as traffic, weather, or technical problems.

**Fig. 4.4** An example for color-coding the density (in the drawing plane) of curves of Power Spectral Density vs. period: a PDF diagram. IRIS DMC, Seattle.

**Table 4.1** Noise power spectral densities at selected periods and in different units which define the new global low-noise model (NLNM) as given by Peterson (1993). Peterson published values for  $P_a$  [dB] only. The respective numbers for ground acceleration ( $P_a$ ), velocity ( $P_v$  and  $P_v$ ) and displacement ( $P_d$  and  $P_d$ ) have been calculated using Eqs. (4.4) to (4.8). Between the listed periods the values are to be linearly interpolated in a PSD-logT diagram.

### 4.3.2 Instrumental self-noise

Instrumental self-noise was no problem with classical seismographs of relatively low magnification and with large masses. According to Wielandt (see Chapter 5, section 5.5) the Brownian (thermal) motion of the seismic mass is a limiting factor only when the mass is very small (less than a few grams). Presently manufactured observatory-grade seismometers have sufficient mass to make the Brownian noise negligible against noise from other sources. However, all modern seismographs use semiconductor amplifiers. They produce, like other active (power-dissipating) electronic components, continuous electronic noise. Its origin is manifold but ultimately related to the quantization of the electric charge. Electromagnetic transducers, such as those used in geophones, also produce thermal electronic noise (resistor noise, Johnson noise). The contributions from semiconductor noise and resistor noise are often comparable, and together limit the sensitivity, i.e., the achievable resolution, of the system. In sections 5.5.6 and 5.5.7 Wielandt discusses self-noise of short-period electromagnetic seismographs and of modern broadband force-balance seismometers.

It is not possible to distinguish between ground noise and instrumental self-noise in the signal recorded from a single instrument. To identify the presence of instrumental noise one can run two or more instruments close to each other on the same pier (so-called **Huddle test**). After

correction for the transfer function of these instruments the ground noise will appear in their records as being coherent. Consequently, the difference signal between the various instruments will represent the incoherent part produced by the instruments themselves. However, it remains the question which of the instruments contributes at what degree to the difference signal? In order to distinguish between the contributions from these seismometers Sleeman et al. (2006) proposed a Huddle test with three seismometers. The power spectral density of self-noise of seismometer 1 then is

$$(4.12) \quad N_1(f) = P_1(f) [1 - (C_{12}(f) \cdot C_{13}(f))/C_{32}(f)]$$

where  $f$  = frequency,  $P_1(f)$  = power spectral density of the output of seismometer 1, and  $C_{kl}(f)$  = coherence spectrum for seismometers  $k$  and  $l$ .

Besides their more or less stationary self-noise, seismometers occasionally produce transient disturbances. They may originate in stressed mechanical parts, in slightly defective semiconductors, or in outgassing porous materials. The level of instrumental noise also depends on the installation. Only part of the instrumental noise is self-noise in a strict sense. Another part can be eliminated by careful shielding against environmental disturbances. For identifying and measuring instrumental noise see Chapter 5, sections 5.5.6 and 5.5.7. Figure 4.5 shows typical levels of self-noise for short-period and broadband seismometers.

**Fig. 4.5** Typical self-noise of different seismometer types in comparison with the NLNM (thin black curve). Black: a short-period, passive Sensonics Mk3 seismometer with a low-noise preamplifier (predicted; compare the theoretical curves for different circuits in section 5.5.6 of Chapter 5). The resolution can be improved by using a larger seismic mass as in the Geotech GS-13 or some historical electromagnetic seismometers. Red: typical performance of well-installed VBB seismometers (such as STS2, Trillium 240, Guralp CMG-3T, or Reftek 151-120). Blue: at very low seismic frequencies, the STS1 (originally designed in 1975) is still the most sensitive broadband seismometer when properly installed. The STS1 is the primary sensor of the Global Seismic Network (GSN).

## 4.4 Comparing spectra of transient and stationary signals

### 4.4.1 Bandwidth and amplitude

For the purpose of the following discussion, we must subdivide the signal categories “transient” and “stationary” further: the transient signals into impulsive and oscillatory ones, the stationary signals into random signals (noise) and monochromatic sinewaves. A typical seismogram, especially a dispersed train of surface waves, are in the “oscillatory” category. Impulsive seismic signals are rare in nature but at least theoretically, the seismic signal near the focus of an earthquake should be impulsive. Ambient seismic noise is often a superposition of all types, the “random” components being due to a large number of independent sources (traffic, wind, waves in the ocean), “transient” components being caused by identifiable sources such as passing cars, and nearly monochromatic components originating from machinery such as sawmills and pumps.

When the PSD of a stationary signal is constant over the bandwidth of a seismograph or a filter and we reduce the filter bandwidth, then the signal power is proportional to the bandwidth because it is the integral of a constant power density over the bandwidth. The rms amplitude of the signal, which is the square root of the power, must therefore be proportional to the square root of the bandwidth. This explains why a “spectral amplitude density” cannot be generally defined; such a definition would imply that the amplitude is generally proportional to the bandwidth, which it is not. It may nevertheless be so in special cases. The peak amplitude of an impulsive signal can be proportional to the bandwidth when the width of the pulse is inverse to its bandwidth so that the total energy does not increase as the square of the peak amplitude. On the other hand, the peak amplitude of a sweep signal (a sinewave with decreasing or increasing

**Fig. 4.6** Each trace shows three signals with identical amplitude spectra but different phase spectra. All traces were obtained by band-pass filtration of a signal with a constant Power Spectral Density with a Gaussian filter whose center frequency was 4 Hz and total 1/e-bandwidth 2 Hz (top), resp. 1 Hz (bottom). The phase was chosen so that the complex spectrum represented an impulsive signal (a *wavelet*, black), random noise (red), and a sweep (blue). The Gaussian wavelet is the shortest pulse that can be obtained in the given bandwidth. As discussed above, its peak amplitude is proportional to the bandwidth, that of the sweep is (almost) constant, and that of the noise is roughly proportional to the square root of the bandwidth. When the bandwidth is reduced, the pulse becomes broader, the noise smoother, and the sweep shorter.

frequency) may be nearly independent of the filter bandwidth. In this case the width of the signal in time decreases with the bandwidth, and again the total energy is proportional to the bandwidth. Fig. 4.6 illustrates the effect of bandwidth on the peak amplitude of different signal types. Consequences for the evaluation of seismograms are discussed in section 4.5.

#### 4.4.2 The dynamic range of a seismograph

The **usable dynamic range** of a seismograph is in principle defined as the range of amplitudes between the smallest and the largest recordable signal. The ability to record small seismic signals is limited by ambient seismic noise, self-noise of the sensor and the digitizer, and non-seismic environmental noise to which the sensor responds. With this definition the smallest recordable signal does not only depend on technical properties of the instrument but also on seismic noise and other local conditions. For large signals a limit is reached when signals are clipped or otherwise unacceptably distorted. This limit is called the operating range of the instrument.

This definition of the dynamic range may seem clear and obvious, but it is not. The problem is that both noise and clip levels are frequency-dependent, and we must compare them in different frequency bands. However, as we have just seen, narrowing the bandwidth can change the amplitude ratios when the signals are not of the same type. The dynamic range not only depends on frequency but also on the bandwidth. We cannot define it as a function of frequency alone. This becomes clear when we investigate the detectability of a pure sinewave in the presence of random noise. An early discussion of this topic with a view to quantization noise was published by Zörn (1974).

Theoretically, no matter how small the amplitude of a sinewave is, it can always be extracted from random noise provided that we can observe the signals over an unlimited time. We can reduce the amplitude of the noise below any given level by reducing the bandwidth while the amplitude of the sinewave remains the same – we must however wait for the response of the filter to the sinewave to reach a steady state. So the dynamic range of a sensor for sinusoidal signals is theoretically infinite. A meaningful definition of the dynamic range must refer to a seismologically useful finite bandwidth in which all signal amplitudes are compared, for example, a bandwidth of one octave or one-half octave around each frequency. The bandwidth should be small enough so that distinguishable signals (such as primary and secondary microseisms, see paragraph 4.6.1) can be resolved on the frequency scale, but large enough to preserve their amplitude. (Some remarks on this topic are also found in paragraph 4.5.2.) Equivalently, considering the uncertainty principle of the Fourier transformation, one could as well specify a realistic time of observation, which cannot be smaller than a few cycles of the signal. This involves some arbitrariness and therefore it is necessary to explain what “dynamic range” exactly means in a specific case. Evans et al. (2010) suggest a particular choice that could be used as a standard.

In contrast to classical analog recordings on paper, which had a dynamic range of some 40-50 dB only, modern digital data loggers with a 24 bit ADC (Analog-to-Digital Converter; see Chapter 6) allow digital recordings with a dynamic range of  $6 \times 24 = 144$  dB. This allows to cover a rather wide range of signal amplitudes and still to resolve seismic noise at the NLNM level (see Fig. 4.7). Covering a range of 144 dB in analog form would correspond to an amplitude range between 1 mm and 16 km!

### 4.4.3 Representing clip levels, signals, and noise in the same diagram

Once we have decided to represent seismic or instrumental noise by its amplitude in a small but seismologically useful bandwidth, we can at least approximately represent clip levels, typical amplitudes of seismic signals, and noise levels in the same diagram. Figure 4.7 is an example. In this case the author of the figure has chosen to annotate the vertical axis with “equivalent earth peak acceleration”, which is perfect to describe clip levels, adequate to describe expected amplitudes of earthquake signals, and a bit awkward for noise because no simple relationship exists between its peak and rms amplitudes. Under certain assumptions, however, an “average peak amplitude” of the noise can be defined, which has been done here. The assumed bandwidth is 1/3 octave.

Alternatively, one might express all signals as rms amplitudes. This would be perfect for stationary noise, a bit inconvenient for clip levels (because the rms amplitude must be multiplied with  $\sqrt{2}$  to obtain the peak amplitude of a sinewave), and awkward for seismic signals because their rms amplitude depends on the averaging time. It makes no sense to average the energy present in, say, one-half octave over the whole length of the seismogram since that energy is usually concentrated in a much shorter interval. One would rather determine the rms amplitude from the largest few cycles at each frequency. Despite the inherent arbitrariness, this kind of diagram has proved very useful for a graphical representation of seismograph performance.

**Fig. 4.7** A representation of the bandwidth and dynamic range of conventional analog (WWSSN short- and long-period) and digital broadband seismographs (STS1/VBB and STS2 with good shielding; see DS 5.1 and IS 5.4). The depicted lower bound is determined by the instrumental self-noise. The scale is in decibels (dB) relative to  $(1 \text{ m/s}^2)^2$ . Noise is measured in a constant relative bandwidth of 1/3 octave and represented by “average peak” amplitudes equal to 1.253 times the RMS amplitude. NLNM is the global New Low Noise Model according to Peterson (1993). Modified version of Fig. 7.48 in Chapter 7. Amplitudes of typical signals according to J. M. Steim (in blue).

#### 4.4.4 Approximate conversion of power densities into recording amplitudes

According to Aki and Richards (1980) the *maximum* amplitude of a wavelet  $f(t)$  near  $t = 0$  can be *roughly approximated* by the product of what they call “amplitude spectral density” and the bandwidth of the wavelet, i.e.,

$$(4.13) \quad f(t)_{t=0} = |F(\omega)| \sqrt{2(f_u - f_l)}$$

with  $f_u$  and  $f_l$  being the upper and lower corner frequencies of the band-passed signal. (Remember that such an approximation is only possible for signals whose energy is maximally concentrated in time.) Likewise, if the power spectral density of noise is defined according to Eq. (4.5) then we get for the *mean square amplitude* of noise in the time domain:

$$(4.14) \quad \langle f^2(t) \rangle = 2P(f_u - f_l)$$

This is of course a simplified version of the general rule that the power spectral density (PSD) must be integrated over the passband of a filter to obtain the power (or *mean square amplitude*) at the output of the filter. The square root of this power is then the *root mean square* (RMS) or effective amplitude

$$(4.15) \quad a_{\text{RMS}} = [2P \times (f_u - f_l)]^{1/2}$$

If the power spectral density is defined according to the engineering approach (see 4.2.3.1) as  $P_e = 2P$ , then

$$(4.16) \quad a_{\text{RMS}} = [P_e \times (f_u - f_l)]^{1/2}$$

We note again that stationary signals must be characterized by their PSD, and **specifying seismic noise by its RMS amplitudes is meaningless without definition of the bandwidth**. The values given by the NLNM and NHNM in Fig. 4.3 and Tabs. 4.1 and 4.2, respectively, follow the engineering convention. For consistency, we will use this convention for the rest of this chapter.

For the reasons discussed in section 4.4, it is often necessary to represent the amplitude of noise (whether rms or average-peak) in a **constant relative bandwidth RBW** over the whole frequency range. This means, the bandwidth  $B$  around each frequency  $f_0$  is a fixed fraction or multiple of  $f_0$ . The lower and upper band limits,  $f_l$  and  $f_u$ , are chosen so that  $f_0$  is the geometric mean of the two (so  $f_0$  appears in the middle between  $f_l$  and  $f_u$  on a logarithmic frequency scale). When the bandwidth is  $n$  octaves or  $m$  decades ( $n$  and  $m$  normally being fractions, not integers), then the following relationships hold:

$$(4.17) \quad f_l = 2^{-n/2} f_0, \quad f_u = 2^{n/2} f_0, \quad \text{RBW} = 2^{n/2} - 2^{-n/2} \text{ and } B = (2^{n/2} - 2^{-n/2}) f_0$$

and (4.16) can be written as

$$(4.18) \quad a_{\text{RMS}} = [P_l \times (f_u - f_l)]^{1/2} = [P_e \times f_0 \times (2^{n/2} - 2^{-n/2})]^{1/2} = (P_e \times f_0 \times \text{RBW})^{1/2}$$

Octaves can be converted easily into decades and vice versa by using the relation

$$(4.19) \quad m = n \cdot \log_{10}(2) = n \cdot 0.3010$$

Aki and Richards (1980, vol.1, p. 498) converted PSD into ground motions by putting the bandwidth of the noise signal at half the considered (center) frequency, i.e., by assuming  $f_u - f_l = 0.5 f_0$ . This corresponds to a relative bandwidth of roughly 2/3 octave. Using the definition of power on which Eq. (4.14) is based they obtained  $a_{\text{RMS}} = (P \times f_0)^{1/2}$ .

**Table 4.3** Bandwidth  $B$  of typical octave and decade filters centered at  $f_0$ .

| Octaves | $B$         | Decades | $B$         |
|---------|-------------|---------|-------------|
| 1       | $0.707 f_0$ | 1       | $2.846 f_0$ |
| 2/3     | $0.466 f_0$ | 1/2     | $1.215 f_0$ |
| 1/2     | $0.348 f_0$ | 1/3     | $0.786 f_0$ |
| 1/3     | $0.232 f_0$ | 1/6     | $0.386 f_0$ |

Other authors (e.g., Fix, 1972; Melton, 1978) have used an integration bandwidth of 1/3 octave (a standard bandwidth in acoustics) for computing RMS amplitudes from PSD. Melton reasoned that this is nearly  $\pm 10\%$  about the center period in width and thus close to the tolerance with which an analyst can measure the period on an analog seismogram. Therefore, using a 1/3 octave bandwidth seemed to him a reasonable convention for calculating RMS noise amplitudes from PSD. The differences, as compared to RMS values based on 1/4 or 1/2 octave bandwidths, are less than 20%. But 1/3 octave amplitudes will be only about 70% or 50% of the respective RMS amplitudes calculated for 2/3 or 4/3 octave bandwidth, respectively. Typical response curves of short-period narrowband analog seismographs for recording transient teleseismic body-wave onsets have bandwidths between about 1 and 2 octaves. For deriving spectral magnitudes, Duda and Kaiser (1989) filtered broadband records with one octave wide bandpasses in intervals of one octave distance with center periods of 0.25 s, 0.5 s, ... 32 s, and 64 s; see Fig. 3.55 in Chapter 3). Fig. 4.8 represents the NLNM (compare Fig. 4.3 ) as rms amplitudes in a constant relative bandwidth of 1/6 decade.

**Fig. 4.8** The USGS New Low Noise Model, here expressed as RMS amplitudes of ground acceleration in a constant relative bandwidth of one-sixth decade, corresponding approximately to 1/2 octave (see Tab. 4.1). A bandwidth of 1/6 decade extends from 82.5% to 121% of the central frequency  $f_0$ . The corresponding values for 1/2 octave are 84% and 119%.

There is a 95% probability that the instantaneous amplitude of random noise with a Gaussian amplitude distribution will lie within a range of  $\pm 2a_{\text{RMS}}$ . Peterson (1993) showed that both broadband and long-period noise amplitudes follow closely a Gaussian probability distribution. This is true for largely natural ambient noise, often not, however, for short-period and broadband noise in urban and industrialized areas. There the noise is often dominated by transient or periodic signals (see, e.g., Figs. 7.17, 7.19, and 7.21 in Chapter 7; also Groos and Ritter, 2009 and section 4.6.3). Yet, in case of a Gaussian probability distribution, the absolute peak amplitudes of the narrowband filtered signal envelopes should follow a Rayleigh distribution. In the case of an ideal Rayleigh distribution the theoretical *average peak amplitudes* (APA) are  $1.253 a_{\text{RMS}}$ . From test samples of narrowband filtered VBB and LP noise records Peterson (1993) measured APA values between 1.194 and 1.275. Therefore, RMS amplitudes in 1/6-decade bandwidth correspond approximately to average peak amplitudes in 1/3 octave bandwidth. An example: According to Fig. 4.8 the minimum vertical ground noise between 10 and 20 s is at -180 dB relative to  $1\text{m/s}^2$ . This corresponds to average peak amplitudes of  $10^{-180/20} \text{m/s}^2 = 1 \text{ nm/s}^2$  in 1/3 octave bandwidth. Accordingly, the total average peak amplitude in this one octave band between 10 and 20 s is approximately  $\sqrt{3} \text{ nm/s}^2$ .

E. Wielandt offers an interactive program NOISECON which can be downloaded via the link from the NMSOP-2 front page to the listing **Download programs and files**. It converts noise specifications into all kinds of standard and non-standard units and compares them to the USGS NLNM. EX 4.1 provides exercises by hand for calculating RBWs and transforming PSDs into  $a_{\text{RMS}}$  for various kinematic units and bandwidths. It is complemented also by several exercises combining eye-estimates and NOISECON applications for interpreting and converting noise spectra.

## 4.5 Seismograph response and waveform

### 4.5.1 Empirical case studies

While in recordings of type A with four-octave bandwidth, the first half cycle contains the largest amplitude, the maximum amplitude in records with 1/2 octave (type A') and one octave bandwidth (type Tr) is reached only at the third half-swing. Also, the first motion amplitude in the one octave record Tr is strongly reduced as compared to that in record A with four octave bandwidth, despite having nearly the same peak magnification. Accordingly, we have to consider that in narrowband records of high magnification (as with WWSSN short-period seismographs; bandwidth about 1.5 octaves) the reduced first motion amplitudes might get lost in the presence of noise. Since reliable first motion polarity readings are crucial for the determination of fault plane solutions (see section 3.4 in Chapter 3) and discriminating earthquakes from explosions, narrowband recordings might result in an unacceptable loss of primary information.

Fig. 4.9 shows earthquake P-wave onsets recorded by short-period seismographs with 1-Hz seismometers but amplitude response curves of different bandwidth. The maximum amplitude of the P-wave onset in the – as compared to the filter in Fig. 4.11 – more narrowband Tr record is only about 1/2 of that in record A although seismographs have nearly the same peak magnification at 1 Hz for steady-state harmonic oscillations. And in record A' the maximum amplitude is only twice as large, even though the A' instrument has four times larger peak amplification than instrument A.

**Fig. 4.9** Left: Displacement amplitude magnification curves of three traditional analog types of short-period seismographs used at seismic station MOX with 1/2 octave (type A'), one octave (Tr - trigger seismograph) and four octave bandwidth (type A), respectively; right: records with these seismographs of a P-wave onset of a deep earthquake at an epicentral distance of  $72.3^\circ$  and hypocentral depth of 544 km (copied from Bormann, 1973).

The following figures, 4.10 to 4.14, illustrate the difficulty of interpreting narrowband seismograms correctly with respect to polarities, amplitudes, and the presence and onset times of secondary arrivals.

**Fig. 4.10** A medium-period velocity-proportional digital broadband record (bandwidth almost 6 octaves between 0.07 – 4 Hz;) at station MOX of an underground nuclear explosion at the Nevada test site (upper record trace), and the same signal filtered with a 4-octave and 2-octave bandpass filter (middle and lower record trace). The positive first motion (to be expected from an explosion) is clearly seen in the BB record despite of the low SNR, but it is buried in the noise of the 2 octave record despite the general SNR improvement due to narrowband filtering. The different absolute amplitude levels in the three records have been normalized to the same peak amplitude.

**Fig. 4.11** Unfiltered (black) and filtered (red) local event waveform of a broadband record (Guralp CMG, 60s–50 Hz) using a 3rd order Butterworth bandpass filter (2–10 Hz). In the more narrow-band high-frequency filtered record the amplitude of the first oscillations is strongly reduced and the phase significantly shifted. The negative first motion, still distinct in the broadband record, is no longer recognizable (copy of Fig. 16.25 in Chapter 16 with permission of the authors Küperkoch et al., 2012)

This systematic underestimation of amplitudes of transient body-wave onsets of short duration in narrowband records - and thus of related magnitude estimates within the first few cycles as for many mb data (Chapter 3, section 3.2.5.2 and Fig. 3.46) - has been a matter of considerable debate between the American and Russian delegations in the early Geneva talks to achieve a Comprehensive Nuclear-Test-Ban Treaty (CTBT). In the Soviet Union standard seismographs with amplitude characteristics of type A (2 to 4 octaves) and broadband characteristics of type Kirnos with about 7 octaves bandwidth (Fig. 3.20 in Chapter 3 and Figure 1 in IS 3.7) were used to determine body-wave magnitudes, whereas American-designed WWSSN stations had a bandwidth of only about 1.5 octaves, and short-period P-wave amplitudes were measured within the first few cycles only for mb magnitude determinations (Engdahl and Gunst, 1966). A consequence of these differences in magnitude determination was that the American delegation reported a much larger number of weak, unidentified seismic events per year than the Soviet delegation and therefore felt that they required hundreds of U.S. unmanned stations on Soviet territory as well as the possibility for on-site inspections. This blocked, amongst other reasons, the agreement on a comprehensive test-ban treaty for two decades. Today these problems are more of historical interest. Present days analysts may filter digital broadband data as desired. But it remains a problem to decide what filter is appropriate for solving best the given task. Therefore, analysts should be aware of both the reasons and possible size of filter effects. For assuring globally compatible magnitude data, however, the International Association of Seismology and Physics of the Earth's Interior (IASPEI, 2005 and 2013 and IS 3.3) has now agreed on some classical filter standards (such as Wood-Anderson, WWSSN-SP and WWSSN-LP) to be applied before measuring the amplitudes and periods for the most widely used types of magnitudes while other responses, such as the Kirnos-D displacement broadband, have proven to be best suited for teleseismic secondary phase recognition and onset time picking.

A narrower bandwidth causes a longer and more oscillating record of an impulsive onset. This makes it difficult to recognize, in narrowband records, secondary onsets following closely behind the first one, e.g., onset sequences due to a multiple earthquake rupture (Fig. 4.12), depth phases in the case of shallow earthquakes or branching/crossing of travel-time curves (see Chapter 2 and Fig. 4.13). But the identification and proper time picking of such closely spaced secondary arrivals may be crucial for a better understanding of complex rupture processes, for improved estimates of hypocenter depth or for studies of the fine structure of the Earth.

It is crucial, therefore, to record seismic signals with as large a bandwidth and with as high a linearity, resolution and dynamic range as possible, thus preserving the primary information with least distortion. Filtering should only be applied afterwards, as required for special purposes. With feedback-controlled broadband seismometers and digital data loggers with 24 bit resolution being common nowadays, this is no longer a problem (see Chapters 5 and 6). In Fig. 4.14 it is clearly recognizable that in the displacement-proportional broadband record of about 10 octaves bandwidth the P-wave onset looks rather simple (negative impulse with only slight positive over-swing of the second half-cycle). Its appearance resembles the expected source displacement pulse in the far field (see Fig. 2.4).

**Fig. 4.12** Short-period records of station MOX according to Bormann (1973) of a multiple rupture event at Honshu ( $D = 88.0^\circ$ ) with different amplitude response characteristics according to Fig. 4.9 left.

**Fig. 4.13** Short-period records of station MOX according to Bormann (1973) of a sequence of core phases corresponding to the travel-time branches PKPdf (PKIKP), PKPbc (old PKHKP) and PKPab (PKP2) (see Chapter 11) with different amplitude response characteristics according to Fig. 4.9 left.

**Fig. 4.14** Records of a deep earthquake ( $h = 570$  km,  $D = 75^\circ$ ) at the Gräfenberg Observatory, Germany. They have been derived by filtering a velocity-proportional digital broadband record (passband between 0.05 and 5 Hz) according to the response curves of some traditional standard characteristics (WWSSN\_SP and LP, Kirnos) while the bottom trace shows the result of computational restitution of the (nearly real) true ground displacement by extending the lower corner period  $T_0$  well beyond 100s (see text) (from Buttkus, 1986; with permission of Schweizerbart [www.schweizerbart.de](http://www.schweizerbart.de)).

#### 4.5.2 Theoretical considerations on signal distortion in seismic records

The basic theory of seismometry is outlined in Chapter 5. For a more comprehensive introduction to general filter theory and its applications in digital seismology (with exercises) see “Of Poles and Zeros: Fundamentals of Digital Seismology” by Scherbaum (3<sup>rd</sup> revised edition, 2007). The book is accompanied by a CD-ROM “Digital Seismology Tutor” by Schmidtke and Scherbaum, which is a very versatile tutorial tool for demonstrating signal analysis and synthesis. E. Wielandt also offers the program **fildemo**. It can be downloaded via the link to *Download Programs & Files* on the NMSOP-2 front page or via Internet (<http://www.geophys.uni-stuttgart.de/~erhard/downloads/> or <http://www.software-for-seismometry.de/>). Therefore, we will not dwell on it further, however, we will illustrate by way of example some of the essential effects of signal distortion by the transfer function of the seismograph. Signal distortion due to wave propagation effects in the Earth and ways how to eliminate at least some of them are discussed in Chapter 2.

As implied by Eq. (4.2), a Dirac (or needle) impulse (see Chapter 5, section 5.2.4) in the time domain is equivalent to a constant (“white”) amplitude spectrum in the frequency domain. Thus, if the far-field seismic source pulse comes close to a needle impulse of very short duration (e.g., an explosion) we would need in fact a seismograph with (nearly) an infinite bandwidth in order to be able to reproduce this impulse-like transient signal. On the other hand, a

monochromatic harmonic signal corresponds to just one spectral line in the frequency spectrum, or, the other way around, if the input signal is a needle impulse with an infinite spectrum but the bandwidth of the seismograph is extremely narrow, then the output signal would not be a needle impulse but rather a slowly growing and decaying sinusoid. Fig. 4.15 depicts these extreme cases and Fig. 4.16 sketches seismographic recordings of an impulse sequence with qualitatively different response characteristics.

According to theoretical considerations by Seidl and Hellweg (1988), the seismometer period  $T_0$  has to be about 100 times larger than the duration  $\tau_s$  of the source-time input function when the source signal shape and its “signal moment” (area under the impulse time curve) is to be reproduced with a relative error  $< 8\%$ . As a rule of thumb, these authors state that the relative error is less than about 10% if  $T_0 > 20 \pi \tau_s$ . This means that extreme long-period seismographs would be required to reproduce with sufficient accuracy the displacement impulse of strong seismic events.

By “signal restitution” (i.e., instrument response correction or “deconvolution”) procedures (Seidl, 1980; Seidl and Stammer, 1984; Seidl and Hellweg, 1988; Ferber, 1989) the eigenperiod of long-period feedback seismometers such as STS1 ( $T_0 = 360$  s) and STS2 ( $T_0 = 125$  s) can be computationally extended - in the case of high signal-to-noise ratio - by a factor of about 3 to 10, and thus the very low-frequency content of the signals can be retrieved. Simulations of standard frequency responses from BB records are available in some of the software packages for signal pre-processing (e.g., PREPROC, Plešinger et al. 1996) or seismogram analysis (e.g., SEISAN, Havskov and Ottemöller, 1999 b, and Seismic Handler by K. Stammer; see <http://ftp.geo.uib.no/pub/seismo/SOFTWARE/SEISAN/> and <http://www.szgrf.bgr.de/sh-doc/index.html>, respectively).

**Fig. 4.15** Sketch of the equivalent representation of a needle impulse (above) and a stationary infinite monochromatic harmonic signal (below) in the time and frequency domain.

**Fig. 4.16** Schematic illustration of the appearance of a sequence of seismic input impulses in record outputs of seismographs with narrow-band displacement response (uppermost trace) and broadband responses (lower traces: broken line – velocity response, full line – displacement response).

Fig. 4.17 shows the very different response of three standard seismograph systems of different damping and bandwidth to a synthetic ground displacement input according to the Brune model of earthquake shear dislocation. The response has been simulated by using the PITSA seismological analysis software of Scherbaum and Johnson (1992). For the amplitude response of the seismographs of type Wood-Anderson (WA), Kirnos, WWSSN long-period (LP) and WWSSN short-period (SP) see Fig. 3.20 in Chapter 3.

**Fig. 4.17** Distortion of a synthetic ground displacement signal according to the Brune model of earthquake shear dislocation (top trace) by standard seismograph systems (for their response curves see Fig. 3.20 in Chapter 3) (from Scherbaum 2001, “Of Poles and Zeros”, Fig. 10.2, p. 167 © Springer; with kind permission from Springer Science+Business Media).

The strong distortion in narrowband recordings after transient onsets is due to their pronounced *transient response* (TR). It is due to the time required by the seismograph system to achieve the values of frequency-dependent magnification and phase shift determined by its amplitude- and phase-frequency characteristics for steady-state harmonic oscillations (see Chapter 5, Fig. 5.3 and Figure 1a and b in IS 5.2). In Fig. 4.17, the effect of phase-shift adaptation during the time of transient response is clearly seen, especially in the records of the WWSSN and Wood-Anderson short-period instruments. Accordingly, the period of the first half cycle appears to be much shorter than that of the second and third half cycle.

Fig. 4.18 compares the response of the same seismographs and of the SRO-LP seismograph with the unfiltered velocity broadband record of the STS2 (see DS 5.1) from an earthquake in the Russia-China border region. The differences in record appearance depending on the response characteristic of the seismograph and the time resolution of the record are striking.

**Fig. 4.18** Record segments from an earthquake at the Russia-China border of 4 min (left) and 30 s duration (right). Uppermost traces: unfiltered STS2 velocity broadband seismogram; other traces: filtered records which simulate the seismograms of standard recordings of type WWSSN-SP, Kirnos, WWSSN-LP and SRO-LP (courtesy of S. Wendt, 2002).

Fig. 4.19 gives an example from a simulation of seismometer response to a monochromatic harmonic ground motion  $w(t)$  of frequency 1 Hz as input. It has been compiled from two different snapshots of an interactive web site demonstration of the Technical University of Clausthal, Germany, which is no longer available. Trace a) has been recorded with a seismometer of eigenperiod  $T_s = 1$  Hz and damping  $D_s = 0.2$  (i.e., resonance at 1 Hz!) while for trace

b)  $T_s = 20$  s and  $D_s = 0.707$ . In the first record the transient response takes about 3 s before the steady-state level of constant amplitudes corresponding to the amplitude response of the seismometer and the constant phase shift of about  $110^\circ$  have been reached (after the 6<sup>th</sup> half cycle). In record b) the transient response takes less than half a second and the seismometer mass follows the ground motion with practically no phase shift. Although the transient response of the 20 s long-period seismometer is much longer than that of the 1 s short-period seismometer, it is not excited here because the signal has very little energy at the eigenperiod.

**Fig. 4.19** Simulation of displacement signal output  $x(t)$  (= relative displacement of the seismometer mass) of a spring-mass pendulum seismometer responding to a monochromatic harmonic ground motion  $w(t)$  of period  $T = 1$  s (thick line in the middle). a) Displacement output of a seismometer with low damping ( $D_s = 0.2$ ) and eigenperiod  $T_s = 1$  s (i.e., resonance); b) Displacement output of a long-period and normally damped seismometer ( $T_s = 20$  s;  $D_s = 0.707$ ). For discussion see text.

**Fig. 4.20** Precursors caused by acausal anti-alias filtering observed on the broadband registration of a local earthquake near Davos, Switzerland (2006/10/24 13:08,  $M_l = 2.6$ ). Sampling frequency is 120 Hz. The precursors become obvious when enlarging the amplitude scale (lower trace). (Copy of Figure 7 in IS 11.4; courtesy of Diehl et al., 2012)

Seismographs are real physical, i.e., causal filters. They respond to analog input signals with unavoidable phase shifts during the transient response time. Digital filters, however, can be designed in a way that they do not produce phase shifts (Scherbaum, 2007; NMSOP Chapter 6). Such systems implement acausal digital anti-alias filters with symmetrical zero-phase shift impulse responses. As a consequence, the onset of impulsive signals (also of signals with frequency close to the Nyquist frequency) may be obscured by artifact precursory oscillations and their true onset becomes difficult, if not impossible, to determine. Fig. 4.20 shows an example. As outlined in IS 11.4, this effect can in principle be minimized by an inverse filtering process, described e.g. in Scherbaum (2001 and 2007). However, this is a nontrivial procedure that requires knowledge of the original anti-alias filter coefficients. Especially for large and inhomogeneous data sets, compiling the correct information can be rather difficult or even impossible.

## 4.6 Characteristics and sources of seismic noise

### 4.6.1 Ocean microseisms

Most of the early 20<sup>th</sup> century seismographs by Wiechert, Mainka, Galizyn, Bosch-Omori, Milne-Shaw and others were medium-period broadband systems. The more sensitive ones with 100 to 500 times magnification were already able to record the ever-present ground motions with peak amplitudes around 6 s which constitute the background noise for any seismic measurement. They were termed microseisms. Such recordings were first reported by Algue in 1900. Wiechert (1904) proposed at the second international seismological conference that these microseisms are caused by ocean waves on coasts. Later it was found that one must discriminate between: a) the smaller primary ocean microseisms with periods between 10 and 20 s, typically around  $14 \pm 2$  s and b) the secondary or *double frequency microseism* which is related to the main noise peak around  $6 \pm 2$  s (see Fig. 4.3, Fig. 4.4, and Fig. 4.5).

Primary ocean microseisms are generated only in shallow waters in coastal regions. Here the wave energy can be converted directly into seismic energy either through vertical pressure variations, or by the smashing surf on the shores, which have the same period as the water waves ( $T \approx 10$  to 16 s). Haubrich et al. (1963) compared the spectra of microseisms and of swell at the beaches and could demonstrate a close relationship between the two data sets. Energy is transferred between ocean waves and seismic waves through non-linear interaction of ocean waves and bathymetry (Hasselmann, 1963). Measurements from instruments in coastal regions show spectral peaks that track ocean wave frequencies incident at the coast, although this energy decays rapidly inland (Haubrich and McCamy, 1969). The peak is also called the single-frequency peak because it mimics swell frequencies. In the center of continents or of an ocean basin, the single-frequency peak is related to storm waves on remote coastlines (Cessaro, 1994). The relative stability in amplitude for continental sites around the globe suggests persistent, stable sources. Holcomb (1998) also reports on a persistent peak of unknown origin in the noise spectrum at 26 s period. The signals are largest during the southern winters and the amplitude of the peak is correlated between sites worldwide.

Contrary to the primary ocean microseisms, the secondary ocean microseisms could be explained by Longuet-Higgins (1950) and Hasselmann (1963) as being generated by the superposition of ocean waves of equal period traveling in opposite directions, thus generating standing gravity waves of half the period. These standing waves cause non-linear pressure

perturbations that propagate without attenuation to the ocean bottom and couple there into an elastic wave of much larger wavelength and higher phase velocity if the propagation directions are nearly opposite. The area of interference X may be off-shore where the forward propagating waves, generated by a low-pressure area L, superpose with the waves traveling back after being reflected from the coast (Fig. 4.21b). But it may also be in the deep ocean when the waves, excited earlier on the front side of the low-pressure zone, interfere later with the waves generated on the back-side of the propagating cyclone. Microseisms are mostly recorded with periods between 5 and 9 sec and are the result of energetic ocean waves between 10 and 18 sec period. Horizontal and vertical noise amplitudes of marine microseisms are similar. The particle motion is dominantly of Rayleigh-wave type, i.e., elliptical polarization of the particle motion in the vertical propagation plane. But some energy is present also as body waves, and heterogeneous Earth structure couples some energy into Love waves.

**Fig. 4.21** Schemes for the generation of a) primary and b) secondary microseisms (for explanations see text). L – cyclone low-pressure area, X – area of interference where standing waves with half the period of ocean waves develop. Copy of Figure 12 from Friedrich et al. 1998 © Springer; with kindpermission from Springer Science + Business Media.

Medium-period ocean/sea microseisms experience low attenuation. They may therefore propagate hundreds of km inland. Since they are generated in relatively localized source areas, they have, when looked at from afar, despite the inherent randomness of the source process, a rather well developed coherent part, at least in the most energetic and prominent component. This allows one to locate the source areas and track their movement by means of seismic arrays (e.g., Cessaro, 1994; Friedrich et al., 1998; Fig. 4.22). This possibility has already been used decades ago by some countries, e.g., in India, for tracking approaching monsoons with seismic networks under the auspices of the Indian Meteorological Survey, although Cessaro (1994) showed that the primary and secondary microseism source locations do not follow the

storm trajectories directly. While near-shore areas may be the source of both primary and secondary microseisms, the pelagic sources of secondary microseisms meander within the synoptic region of peak storm wave activity.

**Fig. 4.22** An example of good spatial coherence of medium-period secondary ocean microseisms at a longer distance from the source area which, in this case, allows rather reliable determinations of the backazimuth of the source area by f-k analysis with seismic arrays (see Chapter 9). Figure a) above shows how the backazimuth determination changed from one day to the next, while b) shows the location of the two storm areas and the seismic array. Observations by at least two arrays permit localization and tracking of the noise-generating low-pressure areas. Copy of Figure 7 from Friedrich et al., 1998 © Springer; with kind permission of from Springer Science+Business Media.

Note that the noise peak of secondary microseisms has a shorter period when generated in shallower inland seas or lakes ( $T \approx 2$  to  $4$  s) instead of in deep oceans. Also, off-shore interference patterns largely depend on coastal geometries and the latter may allow the development of internal resonance phenomena in bays, fjords or channels (see Fig. 4.23) which affect the fine spectrum of microseisms. In fact, certain coastlines may be distinguished by unique “spectral fingerprints” of microseisms.

**Fig. 4.23** Examples for coastline geometries that provide suitable interference conditions for the generation of secondary microseisms. Copy of Figure 13 from Friedrich et al., 1998 © Springer; with kind permission of from Springer Science + Business Media.

## 4.6.2 Noise at the seabottom

### 4.6.2.1 Broadband noise

The microseism mechanism dominates sea floor noise up to frequencies of a few hertz. At slightly higher frequencies (5-10Hz), short-period noise associated with breaking waves may become important (McCreery et al., 1993). While there is little difference in the microseism band between land and the sea floor at longer periods the major difference occurs at frequencies near 1 Hz. Almost always there is much more noise energy around 1 Hz on the ocean floor than on land, often by more than 40 dB (see subsection 4.6.2.2 on short-period ocean noise below). This huge difference has a profound effect on the relative detection thresholds for short-period teleseismic arrivals in these two different recording environments, which is usually much inferior on the ocean floor. For more details on regional/local differences see Webb (2002).

In recent years more and more ocean-bottom seismographs (OBS; see main section 7.5 in Chapter 7 and Havskov and Alguacil) have been deployed in order to overcome the inhomogeneous distribution of land-based seismic stations. But permanent OBS installations are still rare. Generally, the noise level at the ocean bottom, even in deep seas, is higher than that on land (by about 10 to 30 dB) and increases with higher frequencies (e.g., Bradner and Dodds, 1964; Webb, 2002, and Fig. 7.85 in Chapter 7). It can be reduced by installing the OBS in boreholes (see Fig. 4.24). The analogues of wind and air pressure generated noise on the Earth surface are on the ocean floor the ocean currents. According to Webb (1988) they also set up a turbulent boundary layer with advecting pressure fluctuations. However, on the ocean floor the deformation signal decays already completely within a few meters depth below the sea floor because much lower velocities and hence much shorter wavelengths are associated with ocean currents than with wind.

On the ocean bottom, as on land, the secondary microseism noise peak between 0.1 and 1 Hz dominates. Background noise levels in this frequency range tend to be higher in the Pacific than in the Atlantic because of its larger size and its general weather conditions (see Fig. 4.25 below and Figure 2 in Webb, 2002). While short-period body-wave arrivals around 1 Hz have been clearly recorded during calm-weather periods by OBSs in the North Atlantic, even at teleseismic distances, they are recognizable in OBS records in the Pacific only for very large events at distances of less than a few tens of degrees. On the other hand, long-period P, S and surface waves are consistently well recorded by OBSs in the noise minimum between about 0.03 and 0.08 Hz for magnitudes  $6 \pm 0.3$  even at distances  $D > 100^\circ$  (Blackman et al., 1995).

However, because of the generally inferior recording conditions broadband seismic observations from the sea floor remain rare. The primary motivation for installing stations on the sea floor has been to improve the global ray path coverage for tomographic studies of the Earth and for regional studies of seismicity and structure. Yet, significant improvements in global detection thresholds will only be obtained near the sea-floor stations itself. For some significant results see section 7.5.3 of Chapter 7.

**Fig. 4.24** Difference of typical noise power spectra in a borehole installation and a seafloor installation near the borehole of site JT1 (see Fig. 7.80 in Chapter 7). The seafloor observation is noisier than that in the borehole and the horizontal components are much noisier than the vertical (Z) components (after Araki et al., 2004; Figure copied from Fig. 7.71 in Chapter 7; with permission of M. Shinohara, 2013).

**Fig. 4.25** Comparison of ambient seismic noises from seafloor borehole installations: a) for vertical component; b) for horizontal component. WP-1, WP-2 and JT-1 denote observatories in the western Pacific, OSN-1 an observatory off Hawaii (Stephen et al., 1999), and OFP an observatory in the North Atlantic Ocean (Montagner et al., 1994). NHNM and NLNM indicate the Peterson (1993) New High Noise Model and New Low Noise Model, respectively. (Figure copied from Fig. 7.72 in Chapter 7; with kind permission of M. Shinohara, 2013).

According to Webb (1998), horizontal component noise levels on sea-floor sensors can be as much as 60 dB higher than vertical component noise levels at periods near 100 s due to tilt

(e.g., site WP1 in Fig. 4.25). Tilt noise will appear on vertical component records as well if the vertical component sensor is not very precisely oriented with the true plume line. Most vertical component records from the sea floor show evidence of tilt noise due to currents which can be rather strong and thus the records very noisy on shallow-water sites (Romanowicz et al., 1998). However, because of the short wavelengths associated with pressure fluctuations due to ocean-floor currents burial of the sensors just a few meters below the ground will already strongly reduce (up to about 60 dB) the long-period horizontal component noise levels (Webb, 1998). But incomplete burial allowing for convection of sea water in the borehole may deteriorate this positive effect (Beauduin and Montagner, 1996; Vernon et al., 1998). Webb and Crawford (1999) show that sea floor pressure data can be used to remove most of the infragravity wave deformation signal from vertical component OBS data in the band from 0.001 to 0.04 Hz. Improvements of 10-20 dB in SNR for long-period surface waves could thus be achieved at sea-floor stations in the Pacific. For more information about noise and signal recording conditions and installation requirements in an ocean bottom environment see main section 7.5 in Chapter 7 and Webb (2002).

#### **4.6.2.2 Short-period noise (0.5-50 Hz)**

Webb (2002) gives a rather detailed overview of the mechanisms which generate short-period noise on the sea floor and how this noise decays with depth below the sea floor. Here we summarize only some of the most interesting facts and give related references for further reading.

The sea floor in the band from 0.5 to 5 Hz is almost invariably noisier than the typical land site because of microseisms generated by small-amplitude, high-frequency ocean waves that can be produced already by light winds. Such locally generated microseisms maintain for most of the time sea-floor noise levels some 40 dB above land sites. These noise levels "saturate" with little increase above a frequency-dependent saturation wind velocity, which is near 1 Hz about 5 m/s (McCreery et al., 1993). During long intervals of calm winds, however, these noise levels may fall by 20 dB or more (Webb, 1998; Wilcock et al., 1999). Because wind speeds exceed 5 m/s over most sites in the oceans for most of the time, the average sea-floor sites are usually rather noisy near 1 Hz. A notable exception is the Arctic Ocean during winter when the ice cap prevents the excitation of the ocean waves on the surface. Parts of the North Atlantic and Indian oceans can also experience long intervals of near calm conditions during the summer months and may provide quiet sites for detection of short-period body waves (Webb, 1998). In contrast, most sites in the Pacific seem to be noisy most of the time (McCreery et al., 1993).

Installing seismometers within sea-floor boreholes will not necessarily reduce this microseism noise level because the energy is coupled from ocean waves into acoustic waves and then into Rayleigh-wave modes below the sea bed which penetrate down to depths of several kilometres. This is beyond the present range of ocean drilling. However, at shallow depths some SNR improvement is expected because microseisms are scattered by bathymetry and topography at the sediment-basement interface producing short-wavelengths Stoneley shear modes. Their amplitude decay below the sea floor rapidly with frequency and depth (Bradley et al., 1997). But signal levels at depth are also smaller (because of changing impedance). Therefore the resulting improvement in signal-to-noise ratio is near zero at 0.2 Hz, but it increases to more than 10 dB at 5 Hz. Correlation lengths for this type of ocean bottom noise at frequencies above 0.4 Hz, measured between elements of a small-aperture array of OBS, were between 100 and 200 m only (Schreiner and Dorman, 1990).

More high-frequency noise (5-50Hz) on the sea floor tends to be associated with man-made (cultural) sources. A good review of "low-frequency acoustic noise" ( $< 100\text{Hz}$ ), e.g., radiated by marine mammals, can be found in Richardson et al. (1995). While noise frequencies between 5-10 Hz are dominantly wind-generated and caused by wave breaking, most of the cultural ocean noise is more high-frequency and caused by ship traffic (cavitation of propellers and noise from vibration of machinery). Distinct lines associated with generators (50 or 60Hz) or with other machinery (motors, generators, thrusters and pumps, etc.) also make up much of the shipping noise, with noise levels peaking between 10 and 100 Hz. The lowest-frequency components are associated with the rotation of propellers. Large ships such as supertankers produce sharp spectral lines at frequencies of 7 Hz or lower but with many higher harmonics (Richardson et al., 1995). Areas near high-traffic ship routes can be 20-25 dB noisier than regions remote from shipping. Other sources of cultural noise observed on the ocean floor in the seismic band include active seismic sources (airguns) and offshore drilling (Richardson et al., 1995).

For some locations large whales are another natural noise source. Blue and fin whales produce very loud calls at frequencies as low as 16 Hz. They are easily seen locally on sea-floor seismometer records. In some special locations whale calls can be so frequent as to interfere with active source seismic experiments. Also the movement of ice in the polar regions may be a natural noise source in Arctic and Antarctic waters (Richardson et al., 1995).

Most favourable for high-frequency seismic observations is the transition band (5-10Hz), above the microseisms and below the typical shipping noise. It provides relatively quiet conditions that allow the detection of oceanic Pn and Sn phases (also known as Po and So) from moderate magnitude oceanic events to great distances (Butler et al., 1987).

### **4.6.3 Seismic noise on land**

#### **4.6.3.1 Long-period noise**

Ground noise on land at very long period (0.2 to 50 mHz) is usually associated with atmospheric pressure fluctuations. At these very low frequencies, vertical component seismometers react to changes in gravity as the mass of the atmosphere above a site changes with atmospheric pressure. At higher frequencies, the ground deforms under the fluctuating pressures associated with turbulence in the boundary layer of the atmosphere (Murphy and Savino, 1975). If seismometers are not fully sealed they may also experience apparent accelerations due to buoyancy effects on the seismometer mass, and pressure fluctuations may cause long-period horizontal component noise by distorting the case of the seismometer or the walls of the vault (Savino et al., 1972). Long-period seismometers are also sensitive to temperature changes. Therefore, careful installations aim at sealing the sensor from both pressure and temperature fluctuations (see IS 5.4). Zürn and Widmer (1995) showed that vertical component noise levels between 0.2 and 1.7 mHz can be reduced by more than 10 dB by subtracting the scaled, locally recorded pressure signal from the vertical acceleration record, thereby improving the SNR for normal mode observations (see also Beauduin et al. 1996 and Fig. 4.26).

**Fig. 4.26** Linear acceleration amplitude spectra of LaCoste-Romberg Earth tide gravimeter ET-19 records at the BFO observatory in SW Germany after the big Shikotan earthquake of October 4, 1994. Bottom: raw data; Top: barometric-pressure corrected data. Copy of Figure 1 in Zürn and Widmer (1995): On noise reduction in vertical seismic records below 2 mHz using barometric pressure. *Geophys. Res. Lett.*, 22(24), 3537-3540; © American Geophysical Union.

Turbulence in the atmospheric boundary layer produces pressure fluctuations at the Earth's surface that cause significant deformation to depths of a few tens of meters below the surface. This noise source is a primary reason why broadband seismometers at permanent stations are often installed beneath the Earth's surface in shallow boreholes (see section 7.4.5 and Fig. 7.59 in Chapter 7). For instruments on the surface, short-wavelength atmospheric pressure fluctuations produce a large tilt signal that makes the horizontal components particularly noisy. Horizontal noise power may then become significantly larger than vertical noise power. Tilt couples gravity into the horizontal components but much less into the vertical component (see Chapter 5, section 5.3.3 and Figs. 5.8 and 5.9). The ratio increases with the period and may reach a factor of up to 300 (about 50 dB). Therefore a site can be considered as still favorable when the horizontal noise at 100 to 300 s is still within 20 dB above the vertical component noise power, as in Fig. 4.27. Horizontal component noise is mainly due to local tilt, which may also be caused by traffic and wind pressure. At very long periods, deformation of the ground, the seismometer vault, or the building due to insolation gradients (uneven heating by the sunshine) may become noticeable. Generally, recording sites poorly coupled to the ground or on poorly consolidated ground will tend to be noisy, both at long and short periods. Other reasons for increased long-period noise may be air circulation in the seismometer vault or underneath the sensor cover. Special care in seismometer installation and shielding is therefore required in order to reduce drifts and long-period environmental noise (see Chapters 5 and 7 as well as IS 5.4).

For more details also on the causes and phenomena of long-period noise see Webb (2002).

**Fig. 4.27** Seismic noise at the station BNG (Bangui, Central Africa) as compared to the new global seismic noise model by Peterson (1963) (from the FDSN Station Book). The upper and lower broken curves denote the NHNM and NLNM noise models according to Peterson (1993).

#### 4.6.3.2 Short-period noise (0.5 to 50 Hz)

Short-period seismic noise may have natural causes such as wind (wind friction over rough terrain; trees and other vegetation or built-up objects swinging or vibrating in the wind), rushing waters (waterfalls or rapids in rivers and creeks) etc. Wind-generated noise is broadband, ranging from about 0.5 Hz up to about 15 to 60 Hz (Young et al., 1996). But the dominant sources of high-frequency noise are man-made (power plants, factories, rotating or hammering machinery, road and rail traffic, etc.; see sections 7.1 and 7.2 in Chapter 7.) and often referred to as *cultural noise*. Wind-generated noise couples mostly into surface-wave modes, cultural noise, however, couples at least partly into body waves that can propagate also to greater depth (Carter et al., 1991). Cultural noise is in principle avoidable, although it is often impractical to place seismic station sites at sufficient distances away from cities or highways. Some rules of thumb suggest that it may be necessary to site short-period recording stations as far as 25 km from power plants or rock-crushing machinery, 15 km from railways, 6 km from highways, and a kilometer or more from smaller roads. And with respect to moving waters it is recommended to place stations away from moving water between some 60 km for very large waterfalls and dams to 15 km for smaller rapids (see Willmore, 1979 and Tab. 7.5 in Chapter 7). However, noise travels further across competent rock than through alluvial filled valleys. Therefore, "safe" distances may be from 1/2 to 2/3 of the values above, depending on propagation path (Willmore, 1979).

Most of the short-period natural and man-made sources are distributed, stationary or moving. Their contributions, coming from various directions, superpose to a rather complex, more or less stationary random noise field. The particle motion of short-period noise is therefore more erratic than for long-period ocean noise. Nevertheless, polarization analysis, averaged over moving time-windows, sometimes reveals preferred azimuths of the main axis of horizontal particle motion hinting at localized noise sources. Also the vertical component is clearly developed and averaged particle motion in 3-component records indicates fundamental Rayleigh-wave type polarization. A rather popular and cost-effective microzonation method is based on this assumption. It derives information about the fundamental resonant frequency of

the soft-soil cover and estimates local site amplification of ground motion from the peak in the horizontal to vertical component spectral noise ratio (H/V *Nakamura method*; e.g., Nakamura, 1989; Bard, 1999; Parolai et al., 2001 and 2002; Chapter 14).

According to the above, every recording site has different noise characteristics depending on its distance from the ocean, industrial and settlement areas, major infrastructure facilities, the wind climate of the site and the depth of burial of the sensor. At some locations a seasonal cycle is evident due to variations in wind, or water flow in nearby rivers. E.g., according to Fyen (1990), spring runoff raises noise levels by up to 15 dB between 0.5 and 15 Hz at the NORESS array. In settlement and industrial areas a diurnal cycle may dominate due to variable human activity during the day.

High-frequency noise spectra on land during quiet intervals resemble each other at quieter sites. The rather featureless displacement power spectrum follows a power-law dependence in frequency, proportional to  $\approx f^{-2}$  (see Fig. 4.28 and Bungum et al., 1985). This spectral appearance changes drastically due to the strong impact of cultural noise, especially in the frequency band between 1 and 10 Hz (see Fig. 4.31). Wind noise depends on the strength of the wind and the character of the site. Recorded noise power near 1 Hz in a surface vault may increase by 10-20 dB, as compared to records on calm days, when wind speed reaches about 5 m/s. According to Withers et al. (1996) short-period wind noise becomes detectable in records at surface sites far from cultural sources at wind velocities above about 3 m/s and at 4 m/s for subsurface sensors as well (see Fig. 4.29). The primary mechanism by which wind couples into high-frequency noise is probably by the direct action of the wind on trees, bushes, and other structures, although at lower frequency the pressure fluctuations associated with wind can directly drive motions of the ground.

**Fig. 4.28** Spectrum of displacement power spectral density calculated from 6 moving, 50% overlapping intervals of short-period noise records, 4096 samples long each, i.e., from a total record length of about 80 s at a rather quiet site in NW Iran.

**Fig. 4.29** Displacement power noise spectra measured at the surface (upper curves) and at 420 m below the surface in a disused salt mine at Morsleben, Germany (lower curves) on a very quiet day (hatched lines) and on a day with light wind on the surface (wind speed about 4 m/s; full lines).

Cultural noise varies greatly between sites (Fig. 4.34). Noise levels may differ also by 30 dB or even more within a day (e.g., Fig. 4.30 and Fyen, 1990), as well as from day to day. Therefore, it is common to present ensembles of spectra by per-centile ranking to allow discrimination between infrequent very loud sources and more typical background levels (e.g., Bungum et al., 1985). Industrial and traffic noise levels are usually lowest on weekends but increase during holidays because of higher traffic. Sources such as power plants, transformer stations etc. generate narrowband noise, producing energetic spectral lines at 50 or 60 Hz as well as related harmonics and sub-harmonics (e.g., at 30 Hz, 25 Hz, 12.5 Hz) depending on location (Fig. 4.31). The NORESS array data included lines at 6, 12, and 17 Hz due to reciprocating saws in a nearby sawmill (Fyen, 1990), and records at Moxa (MOX) station in Germany have been spoiled over decades by a pronounced 2 Hz peak due to heavy steam engine driving a steel-press for rails at a distance of 16 km. It may be possible to remove some of such narrowband noise through application of digital or analog filters (see section 4.7). Other types of machinery, however, may also produce narrowband peaks in the noise spectra, but with time-variable frequencies as motor speed may vary. These noise sources are more difficult to remove.

Comparisons of noise spectra from surface vaults and subsurface installations in mines (Fig. 4.29) or boreholes (Fig. 4.32) have repeatedly shown significant improvements in SNR for high-frequency phases recorded at depths, sometimes even as shallow as a few meters (e.g., Aster and Shearer, 1991). The signal-to-noise ratio for high-frequency arrivals can be optimized by choosing sites with a lossy blanket of weathered near-surface material (Withers et al., 1996). Large reductions in noise level may also be seen in the first 5 m between the weathered rock of the surface and the more competent rock in the borehole. Wind noise, however, may couple into open boreholes. Therefore, covering open boreholes can reduce wind noise considerably.

**Fig. 4.30** Comparison of relatively quiet sections of vertical component noise records (left; without strong transients) and related power spectra (right) at a reference site in the district capital town of Miene in NW Iran. The measurements were made at different times of the day.

**Fig. 4.31** Noise records and related power spectra near to a transformer house and power line. Note the monochromatic spectral lines around 13, 30 and 50-60 Hz, either induced by the AC current frequency and its lower harmonics and/or caused by the vibration of the transformer.

**Fig. 4.32** Velocity power density spectra as obtained for noise records at the surface (top) and at 300 m depth in a borehole (below) near Gorleben, Germany (courtesy of M. Henger).

Most comparisons of borehole and vault noise levels show 10-30 dB lower noise levels in the boreholes, with most of the reduction in noise level occurring in the first 100 m (Young et al., 1996). Broadband spectral levels fall also with increasing borehole depth but narrow spectral lines due to cultural sources and or waveguide trapping may show less depth dependence (e.g., Galperin et al., 1978). This is also demonstrated by the very different noise decay with depth in typical 1-Hz records made in two deep boreholes in the US (Fig. 4.40). While in a borehole in Texas the noise amplitudes decreased steadily (up to a factor of 30) down to 3000 m depth below surface, they decreased in another borehole in Oklahoma down to about 2000 m only and then increased again towards larger depth. At this greater depth a layer with 22% lower P-wave velocity was found by means of borehole seismic measurements (noise traveling in a low-velocity layer?).

The surface-wave nature of seismic noise (including ocean noise) is the reason for the exponential decay of noise amplitudes with depth, which is not the case for body waves (Fig. 4.33). Since the penetration depth of surface waves increases with wavelength, high frequency noise attenuates more rapidly with depth. In case of Fig. 4.33 the noise power at 300 m depth in a borehole was reduced, as compared to the surface, by about 10 dB, at  $f = 0.5$  Hz, 20 dB at 1 Hz and 35 dB at 10 Hz. Withers et al. (1996) found that for frequencies between 10 to 20 Hz, the SNR could be improved between 10 to 20 dB and for frequencies between 23 and 55 Hz as much as 20 to 40 dB by deploying a short-period sensor at only 43 m below the surface. But both noise reduction and signal behavior with depth depend also on local geological conditions (see 4.6.5). Because of the surface-wave character of short- and medium-period noise, the horizontal propagation velocity of seismic noise is frequency dependent. It is close to the shear-wave velocity in the uppermost crustal layers, which is about 2.5 to 3.5 km/s for outcropping hard rock and about 300 to 650 m/s for unconsolidated sedimentary cover. This is rather different from the apparent horizontal propagation velocity of P waves and all other steeply emerging teleseismic body-wave onsets.

**Fig. 4.33** Recording of short-period seismic noise (left) and signals (right) at the surface and at different depth levels of a borehole seismic array. Note the significantly larger Pn amplitude closer to the surface. It is due to the surface amplification effect which may reach a factor of two for vertical incident waves. (Figure copied from Bormann, 1966; modified from Broding et al., 1964).

Signals which have a similar waveform and polarization, so that they can interfere constructively, are termed coherent. This is usually the case for seismic signals generated and radiated by a common source process. The degree of coherence is defined by the ratio between the auto- and the cross-correlation of the time series (the cross-correlation is squared and divided by both autocorrelations, to render the result independent of the signal amplitudes). It may vary between 0 and 1. For seismic noise it shows distinct frequency dependence. Spatial coherence (paragraph 4.2.4) may be rather high for long-period ocean microseisms. Accordingly, the correlation radius, i.e., the longest distance between two seismographs for which the noise recorded in certain spectral ranges is still correlated, increases with the noise period. It may be several km for  $f < 1$  Hz but drops to just a few tens of meters or even less for  $f > 50$  Hz. For seismic noise, it is usually not larger than a few wavelengths.

Generally, noise levels increase with higher wind speeds. However, there is apparently no linear relationship between wind speed and the amplitude of wind generated noise. Wind noise increases dramatically at wind speeds greater than 3 to 4 m/s and may reach down to several hundred meters depth below the surface at wind speeds  $> 8$  m/s (Young, 1996). But generally, the level and variability of wind noise is much higher at or near the surface and is reduced significantly with depth (Fig. 4.30). Moreover, while for wind speeds below 3 to 4 m/s, one may observe omnidirectional background noise with relatively large coherence length at frequencies below 15 Hz, the coherence length is strongly reduced at higher wind speeds with increased air turbulence and local wind pressure fluctuations (Withers et al., 1996).

Thus, differences in the frequency spectrum, horizontal wave-propagation velocity, degree of coherence and depth dependence between (short- and medium-period) seismic noise and seismic waves allows to improve the signal-to-noise-ratio (SNR) by installing seismic sensors either at reasonable depth below the surface or by way of data processing (see 4.7).

#### 4.6.3.3 Seismic noise in urban environments

In urban, densely populated and industrialized environment both natural and cultural noise components may play a major role in a wide range of frequencies. Measuring and analyzing urban seismic noise (USN) requires broadband recordings and data analysis. Fig. 4.34 compares the noise power density spectrum measured at the former seismological station in the city of Hamburg, Germany, with the spectrum measured on a hard rock site in a quiet Spa village some 70 km apart.

**Fig. 4.34** Noise power spectra at HAM (upper two curves, red) and BSEG (lower two curves, blue) determined from vertical-component records on August 1, 1994, at daytime (around 10 a.m. local time) and nighttime (around 11 p.m. local time), respectively. (Color version of figure 9 in Bormann et al., 1997 © Springer; with kind permission of Springer Science + Business Media).

From Fig. 4.34 the following conclusions can be drawn: While in a remote quiet urban setting the seismic noise spectrum may decay at night almost monotonously towards higher frequencies the cultural noise activity may increase the daytime PSD for frequencies above 1 Hz by some 10 dB. In contrast, in a very busy industrialized city such as Hamburg, the seismic noise level may be 20 dB to 40 dB higher for frequencies of about 0.5 – 30 Hz and may be reduced during night time by some 2 dB to 10 dB only between 1 Hz and 10 Hz. In the metropolitan city of Berlin the “cultural noise” difference at frequencies exceeding 1 Hz between midday and midnight is nearly constant at 10 dB for all frequencies (see Fig. 7.31 in Chapter 7), but it may be larger at other towns with more pronounced diurnal variability of human and industrial activities.

Groos and Ritter (2009) stated that the generally high variability of USN does not allow to characterize a sample time series of USN comprehensively by single measures such as the standard deviation of a seismic noise series or the PSD at a given frequency. For the metropolitan city of Bucharest, Romania, they calculated long-term spectrograms of up to 28 days duration from broadband seismic recordings. The aim was to identify the frequency-dependent behavior of the time-variable processes that contribute to USN. Based on the spectral analysis of the data in eight frequency ranges between 8 mHz and 45 Hz they proposed a time-domain classification which allows to identify both Gaussian distributed seismic noise time series as well as time series that are dominated by transient or periodic signals due to traffic,

rotating machinery etc. Groos and Ritter (2009) found that only 40% of the analyzed time series are characterized by Gaussian distributed noise and that the most common deviations from a Gaussian distribution are due to large-amplitude transient signals (Fig. 4.35). And most astonishingly, they found significant variations of the statistical noise properties with daytime in the whole frequency range between 0.04 and 45 Hz, i.e., both below and above the microseismic noise peak. This result points to a broadband human influence on USN. The authors recommend to use such automatically derived information from broadband seismic data to select suitable time windows for H/V noise studies (see Chapter 14) or ambient noise tomography.

**Fig. 4.35** Time series (left-hand panels) and their histograms with the Gaussian distributions (right-hand panels) of vertical-component USN recorded in Bucharest according to Groos and Ritter (2009). Estimated from the mean and the upper boundary of the 68% interval of the corresponding time series. The red and yellow lines in the right-hand panels delimit the 2-sigma and 3-sigma range of the Gaussian distributed time series. Note that the more the time series are dominated by short transient noise signals the more the real amplitude frequency distributions deviate from the respective Gaussian ones. The non-bell shaped multimodal distribution under (e) is due to time series dominated by sinusoidal signals of different dominating frequencies and the asymmetric distribution under (f) is due to the dominance of asymmetric signals in the time series. #### 4.6.4 Signal and SNR variations due to local site conditions

Compared to hard rock sites, both noise and signals may be amplified on soft soil cover. This signal amplification may partly or even fully outweigh the higher noise observed on such sites. Signal strength observed for a given event may vary strongly (up to a factor of about 10 to 30) within a given array or station network, even if its aperture is much smaller than the epicentral distance to the event ( $< 10\text{-}20\%$ ), so that differences in backazimuth and amplitude-distance relationship are negligible (Fig. 4.36).

**Fig. 4.36** Records of a Semipalatinsk event at stations of the NORSAR seismic array (diameter about 90 km). The event is about  $37\text{--}38^\circ$  away. Note the remarkable variations of signal amplitudes by a factor up to 10 (the standard deviation is about a factor of 2) (from Tronrud, 1983a).

Also, while one station of a network may record events rather weakly from a certain source area, the same station may do as well as other stations (or even better) for events from another region, azimuth or distance (e.g., station GWS in Fig. 4.37 left and right, respectively).

**Fig. 4.37** Short-period records of underground nuclear explosions at the test sites of Semipalatinsk (left,  $D$  about  $41^\circ \pm 1^\circ$ ) and Nevada (right;  $D$  about  $81^\circ \pm 1^\circ$ ) at stations of the former East German seismic network. Note the differences in signal amplitudes both amongst the stations for a given event and for the same station pairs, when comparing events in different backazimuth and distance. Also, at right, the compressive first motion is lost at several stations in the presence of noise due to the narrowband one-octave recording. Small numbers on the x-axis are seconds, while big numbers are minutes.

Fig. 4.38 compares for regional and teleseismic events the short-period P-wave amplitude ratio (left) and SNR (right) of two stations of the German Regional Seismic Network (GRSN). In the same azimuth range, but at different epicentral distances, station BRG may record both  $> 3$  times larger as well as  $> 3$  times smaller amplitudes than station MOX. This corresponds to magnitude differences up to one unit! The SNR ratio BGR/MOX also varies by a factor of 3 and more, depending on azimuth and distance of events. Therefore, optimal site selection can not be made only on the basis of noise measurements. Also, the signal conditions at possible alternative sites should be compared.

**Fig. 4.38** Pattern of the relative short-period P-wave amplitudes (left) and related SNR (right) at station BRG normalized to those of station MOX (170 km apart) in a distance-azimuth polar diagram. Modified version of Figure 7 from P. Bormann et al., 1992 © Elsevier; with permission from Elsevier.

However, differences in local signal conditions may become negligible in long-period recordings and thus play a lesser role in site selection for broadband networks and arrays. This is demonstrated with Fig. 4.39. Plotted are the low-pass ( $f_c = 0.1$  Hz) filtered 3-component traces of an earthquake in Iran, recorded at the stations HAM and BSEG. According to Fig. 4.34 the short-period noise at BSEG was about 20 to 40 dB lower than at station HAM, yet, the long-period SNR in the Z-component of HAM was comparably good and even better in the horizontal components because of better tilt noise avoidance than in the temporary installation at BSEG at the time of the records. Thermal shielding and reduction of tilt noise have the highest priority in long-period and very broadband installations (see IS. 5.4).

**Fig. 4.39** Low-pass filtered ( $f_c = 0.1$  Hz) long-period 3-component records at the seismic stations BSEG and HAM of the Iran earthquake. For the broadband noise spectra of these two station see Fig. 4.34. Copy of Figure 20 from Bormann et al., 1997 © Springer; with kind permission from Springer Science+Business Media.

#### 4.6.5 Installations in subsurface mines, tunnels and boreholes

As shown in Fig. 4.29, Fig. 4.32 and Fig. 4.33, short-period seismic noise is strongly reduced with the depth in sensor installations in mines and boreholes. However, when installing seismometers at depth, one must also consider effects on the signal. Generally, amplitudes of seismic body waves recorded at the free surface are systematically increased by as much as a factor of two, depending on the angle of incidence and wavelength (see Exercise 3.4, Tab. 1). On the other hand, at a certain depth, destructive interference between incoming and surface-reflected waves may cause signal reduction. Therefore, because of the “free-surface effect”, peculiarities of the local noise field and geological conditions, the SNR does not necessarily increase steadily with depth. Fig. 4.40 compares two case studies of short-period signal and noise measurements in two deep boreholes in the USA.

The ratio of the noise in the borehole and at the surface,  $S_B/S_{OF}$ , differs in the two boreholes. Its mean value drops in the Texas borehole to  $1/10^{\text{th}}$  at about 1500 m depth and increases again to  $1/2$  of its surface value at 3000 m depth, while in the Oklahoma borehole it drops to about  $1/3$  at about 1000 m depth and then remains roughly constant thereafter. Accordingly, we have no SNR improvement (on average) in the Texas borehole down to about 1000 m depth, but then the SNR increases to a factor of about 15 at 3000 m depth. Contrary to this, the SNR increases by a factor of 3 in the Oklahoma borehole within the first 800 m, but then remains roughly constant (ranging between 1 and 5) up to 3000 m depth.

**Fig. 4.40** Depth dependence of the signal-to-noise ratio (SNR). The top curve in both figures shows the improvement in SNR. The abbreviations are: SB/SOF: Ratio of signal in borehole and at the surface; NB/NOF: Ratio of noise in borehole and at the surface. SNR improvement in a borehole in Texas is shown left and in Oklahoma right. (Figure copied from Bormann, 1966; redrawn from Douze, 1964).

Thus there is no straight-forward and continuous SNR improvement with depth. It may depend also on local geological and installation conditions. Nevertheless, we can generally expect a significant SNR improvement within the first few hundred meters depth. This applies particularly to borehole installations of long-period and broadband sensors which benefit already at much shallower depth greatly from the very stable temperature conditions and strongly reduced tilt noise, also in hard rock tunnels. For more information about tunnel installations see section 7.4.3 in Chapter 7.

**Fig. 4.41** Recording of a teleseismic event at  $D = 80^\circ$  at a) the surface and b) at 3000 m depth in the Texas borehole (see Fig. 4.40 left). The SNR in record b) has improved by a factor of about 10. Note that signal arrivals in the borehole record are followed by surface reflections (R) about 3 s later (Figure copied from Bormann, 1966; redrawn from Douze, 1964).

In mines or boreholes a depth of 100 m is generally sufficient to achieve most of the practicable reduction by -20 to -30 dB of long-period noise with periods between 30 s and 1000 s) (see Fig. 7.59 in section 7.4.5 of Chapter 7). According to Murphy and Savino (1975) the effect of atmospheric pressure fluctuations on horizontal component noise is reduced by more than 90% at a depth of 150 m. In this context one should also be aware that in records of deep borehole installation the superposition of the first arriving waves with their respective surface reflection may cause irritating signal distortions although they can be filtered out by tuned signal processing (Fig. 4.41). However, for installations less than 200 m deep the travel-time

difference between direct and reflected waves is (in consolidated rock) less than 0.1 s and then usually negligible. Since the cost of drilling and installation increases greatly with depth, no deeper permanent seismic borehole installations have yet been made. In any event, the borehole should be drilled through the soil or weathered rock cover and penetrate well into the compacted underlying rock formations.

## 4.7 Improving the Signal-to-Noise Ratio by data processing

### 4.7.1 Frequency filtering

**Fig. 4.42** Principle of FOURIER transform and bandpass filtering of a seismic record.

**Fig. 4.43** Recording of a long-period trace at a broadband station. The LP trace has a flat velocity response from 360 s to 0.5 s. On the unfiltered trace (top), only the P-phase might be identified, while on the filtered trace (bottom), the signal-to-noise ratio is much improved and several later phases are clearly recognizable since the microseisms have been removed by filtering (courtesy of J. Havskov, 2001).

**Fig. 4.44** Original (bottom) and frequency filtered record (top;  $f = 2.0 - 4.0$  Hz) of an underground nuclear explosion at the Semipalatinsk test site, Eastern Kazakhstan ( $D = 38^\circ$ ) at station 01A00 of the NORSAR array. Time marks in seconds (from Tronrud, 1983b).

When the frequency spectrum of the seismic signal of interest differs significantly from that of the superposed seismic noise, band-pass filtering can help to improve the signal-to-noise ratio (SNR). Fig. 4.42 illustrates the principle and Fig. 4.43 to Fig. 4.45 show examples.

**Fig. 4.45** Isolation of a local  $M_l = 2.2$  earthquake that occurred 32 km away from the Black Forest Observatory (BFO), Germany, by frequency filtering of the raw data of a velocity broadband STS-2 record. Top: 10 min record of raw data; Middle: stretched 1 min record of raw data; Bottom: elimination of the 6 s ocean microseisms by 2-Hz highpass filtering. (Plots by courtesy of Thomas Forbriger).

## 4.7.2 Velocity filtering and beamforming

Often the dominant signal frequencies may coincide with that of strong noise. Then frequency filtering does not improve the SNR. On the other hand, the horizontal propagation velocity of noise, being dominantly surface waves of Rayleigh-wave type, is much lower than that of P waves and also lower than that of teleseismic S waves with a steep angle of incidence. This leads to frequency-wavenumber (f-k) filtering (see Chapter 9) as a way to improve SNR. To be able to determine the horizontal propagation direction and velocity of seismic signals by means of signal correlation, a group of seismic sensors must be deployed. If the aperture (diameter) of the sensor group is within the correlation radius of the signals it is called a seismic array (see Chapter 9); otherwise the group of sensors comprises a station network (see Chapter 8). Assuming that the noise within the array is random while the signal is coherent, even a simple direct summation of the  $n$  sensor outputs would already produce some modest SNR improvement. When the direction and velocity of travel of a signal through an array is known, one can compensate for the differences in arrival time at the individual sensors and then sum-up all the  $n$  record traces (beam forming). This increases the signal amplitude by a factor  $n$  while the random noise amplitudes increase in the beam trace only by  $\sqrt{n}$ , thus improving the SNR by  $\sqrt{n}$ . Fig. 4.46 compares the (normalized) individual records of 13 stations of the Gräfenberg array, Germany with the beam trace. A weak underground nuclear explosion at a distance of  $143.6^\circ$ , which is not recognizable in any of the single traces, is very evident in the beam trace.

**Fig. 4.46** Detection of a weak underground nuclear explosion in the 10 kt range at the Mururoa Atoll test site ( $D = 145^\circ$ ) by beam forming (top trace). No signal is recognizable in any of the 13 individual record traces from stations of the Gräfenberg array, Germany (below) (from Buttkus, 1986; with permission of Schweizerbart [www.schweizerbart.de](http://www.schweizerbart.de)).

### 4.7.3 Noise prediction-error filtering

In near real time, it is possible to use a moving time-window to determine the characteristics of a given noise field by means of cross- and auto-correlation of array sensor outputs. This then allows the prediction of the expected random noise in a subsequent time interval. Subtracting the predicted noise time series from the actual record results in a much reduced noise level. Weak seismic signals, originally buried in the noise but not predicted by the noise “forecast” of the prediction-error filter (NPEF) may then stand out clearly. NPEFs have several advantages as compared to frequency filtering (compare with Fig. 4.47):

- No assumptions on the frequency spectrum of noise are required since actual noise properties are determined by the correlation of array sensor outputs;
- While frequency differences between signal and noise are lost in narrowband filtering, they are largely preserved in the case of the NPEF. This may aid signal identification and onset-time picking;
- Signal first-motion polarity is preserved in the NPEF whereas it is no longer certain after narrow-band or zero-phase band-pass filtering (see section 4.5).

**Fig. 4.47** Records of an underground nuclear explosion recorded at the Uinta Basin small aperture seismic array a) in the beam trace (sum of 10 seismometers), b) and c) after noise prediction error filtering with and without cross correlation (see 4.4.2) and d) after frequency band-pass filtering (1.3 – 5 Hz) (compiled by Bormann, 1966, from data published by Claerbout, 1964).

### 4.7.4 Noise polarization filtering

3-component recordings allow one to reconstruct the ground particle motion and to determine its polarization. Shimshoni and Smith (1964) investigated the cross product

$$(4.20) \quad M_j = \sum_{i=-n}^n H_{i+j} \cdot V_{i+j}$$

in the time interval  $j - n$  to  $j + n$  with  $H$  and  $V$  as the horizontal and vertical component recordings, respectively.  $M$  is a measure of the total signal strength as well as of the degree of linear wave polarization. Eq. (4.20) vanishes for Rayleigh, Love and SH waves. On the other hand, for linearly polarized P and SV waves,  $H$  and  $V$  are exactly in phase and the correlation function becomes  $+1$  for P and  $-1$  for SV waves. The longer the integration time, the better the suppression of randomly polarized noise with a high Rayleigh-wave component. The optimal window length for good noise suppression, while still allowing good onset time picking, must be found by trial and error. Fig. 4.48 gives an example. One great advantage of polarization filtering is that it is independent of differences in the frequency and velocity spectrum of signal and noise and thus can be applied in concert with other procedures for SNR improvement.

**Fig. 4.48** Example of SNR improvement by polarization filtering according to Eq. (4.20) (bottom trace).  $H$  – horizontal component record,  $V$  – vertical component record (modified from Shimshoni and Smith, 1964).

## 4.8 Global detection thresholds

### 4.8.1 Detection thresholds for surface waves and long-period body waves

Webb (2002) discusses on the basis of data and diagram compilations by several authors the detection thresholds on land-based and ocean bottom station sites for seismic events in terms of their moment magnitudes. According to Fig. 4.49a the global noise levels are sufficiently low at most land-based sites to allow the detection of long-period seismic arrivals from large distant earthquakes. Many of the Earth normal modes can be detected at the quieter sites from the largest events as well. Signal- to-noise ratios are estimated by comparing the root mean square (rms) noise levels with model signal amplitudes in  $1/3$  octave bands. Signal levels are estimated for teleseismic distances of  $30^\circ$ . The solid lines relate to surface wave and body wave amplitudes. The broken lines, extending the surface wave curves, represent normal mode amplitudes. Surface wave spectra, however, vary greatly with source mechanism and depth. Accordingly, surface waves from shallow events are barely detectable near  $0.04$  Hz at most sites from events exceeding about  $M_w = 4.5$ , but the detection of lower-frequency surface waves and normal modes requires larger events. Body waves can be detected at most sites at frequencies below the microseism peak from events with  $M_w > 4.5$ . Smaller events can be detected at smaller distances.

**Fig. 4.50** Same as Figure 4.49 for sea-floor sites for (a) vertical acceleration, and (b) pressure with noise levels from an atypically quiet (calm wind) interval (left) and from a more typical noisy (windy) interval (right). Signal amplitudes are modeled for three different values of attenuation ( $t^*$ ). High noise levels near 1 Hz make it difficult to detect short-period teleseismic body wave phases. (Copied from Figure 4 in Webb, 2002; © Academic Press, Amsterdam).

The detection thresholds depend on distance and travel-path as well as wave-type related attenuation. The rapid decrease in microseism noise at frequencies larger than the frequency of the microseism peak means that small changes in the frequency content of seismic phases may be associated with large differences in detection thresholds. S-waves are more attenuated than P-waves (see section 2.5.4.2 and Fig. 2.79 in Chapter 2 as well as the compressional and shear Q tables and formula in DS 2.1). The dominating frequency content of shear waves may therefore be too low in frequency at teleseismic distances to be seen at all above the large amplitudes of the microseism peak. P waves, however, have at teleseismic distances still enough energy around 1 Hz to be seen on records at land sites but not at generally more noisy sea-floor sites. According to Fig. 4.49 the detection thresholds at most land sites for P waves from distant events ( $>30^\circ$ ) will be roughly magnitude Mw 4.0, with slightly lower values for the quieter sites and much higher detection thresholds for the noisier island sites. According to Webb (2002) this is in rough agreement with more careful estimates of detection thresholds for groups of stations. Recent estimates for global event detection thresholds using seismic arrays range from about Mw 3.5 for heavily instrumented areas such as Europe to greater than Mw 4.5 for remote regions of the world's oceans (e.g., Kvaerna and Ringdal, 1999). Fig. 4.49 suggests that all stations will detect S wave arrivals from events as small as about Mw 2.5 at close range (100km).

Efforts to detect small underground nuclear explosions have focused on detecting high-frequency Pn and Sn arrivals at regional distances over continental platforms. Pn is then detectable at frequencies up to 50 Hz at 500 km and at distances up to 1500 km at 10 Hz from magnitude Ml 3.0 events. Also high-frequency oceanic Pn and Sn waves can still be detected over great distances from moderate oceanic events (lower detection threshold mb  $\approx$  4.6) because at their higher frequency the ocean microseism noise is low (Butler et al., 1987). However, at most sea-floor sites the high noise levels near 1 Hz and high attenuation in the oceanic upper mantle allow to detect teleseismic P waves with periods around 1 s only with poor SNR

from events with  $M_w > 7$  (Blackman et al., 1995). However, the lower noise levels within sea-floor boreholes may lower the detection thresholds for short-period teleseismic body waves from the  $M_w = 7.5$ , expected for noisy sea-floor sites with a saturated microseism spectrum, to about  $M_w 6.5$  and detection limits for quiet sea-floor noise conditions should be below  $M_w 5.5$ . Orcutt and Jordan (1986), e.g., reported on detection thresholds from a sensor in a borehole in the western Pacific, which is at a site where light winds are expected more than 73% of the time, suggesting low noise levels near 1 Hz. The lower detection limits increased from about  $m_b = 5.2$  at a distance of  $40^\circ$  to about  $m_b = 5.6$  at  $80^\circ$ . This is consistent with the low-noise model of Fig. 4.3. Fig. 4.50a, combined with a 10 dB SNR improvement due to the borehole installation, particularly if the observations are associated with deep earthquakes from the subduction zones of the western Pacific, with signals propagating along low-attenuation paths.

Wilcock et al. (1999) arrived at similar conclusions with respect to lower detection thresholds in an ocean environment. They investigated wind statistics over the world's ocean-floor ridges to look for regions where long intervals of calm winds are more common. In these quiet regions noise levels will often be 20 dB lower than at typical sites with wind-noise saturation, and thus their associated detection thresholds several magnitude units smaller. Figure 4.50a shows noise in 1/3 octave bands from a site on the sea floor during a typical noisy period and Fig. 4.50 during one of the rare low-wind days from the MELT experiment. Teleseismic detection thresholds at the sea floor depend on attenuation below a site which is represented by the value of  $t^*$  shown on the model curves for P-wave amplitude for earthquakes of magnitudes 5.5, 6.5, and 7.5. The microseism noise spectrum falls quickly with increasing frequency. Therefore detection thresholds for short-period teleseismic P waves are lower. The model curves for  $t^* = 0$  suggest that only the largest earthquakes ( $M_w > 7.5$ ) will be detected at typical noisy sea-floor sites near ridge crests (where attenuation is high). The detection threshold at sites on older oceanic crust, and for arrivals from deep earthquakes for which attenuation is less ( $t^* = 1$ ) are lower ( $M_w \approx 6$ ). Finally, at sea-floor sites that see long intervals with calm conditions overhead (see Fig. 4.50b) the detection threshold may fall as low as  $M_w = 5.5$ . The detection thresholds at local and regional distances for sites on the sea floor are even much lower because of the much higher frequency content of the wave arrivals as compared to that of the microseism peak. Local events with  $M_w$  between -1.5 and 20 have been detected during microearthquake studies on ridge crests.

## Acknowledgments

The authors thank E. Bergman, J. Havskov and E. Hjortenberget for carefully reading the draft for the first edition and for their valuable suggestions which helped to improve the text and a few figures. Still these parts make for most of the revised and amended 2<sup>nd</sup> edition. The new section 4.2 and parts of sections 4.3 and 4.4 are based on lecture notes by E. Wielandt, who also contributed the new Figs. 4.4, 4.5 and 4.6. Thanks go also to two reviewers of the upgraded version of this Chapter for their valuable comments. Th. Forbriger made lecture notes on seismic noise available as well, provided Fig. 4.45 and recommended additional references. J. R. R. Ritter checked the correctness of section 4.3.3.6 on urban noise. Several topically well-fitting figures were reproduced, with proper acknowledgment and permission by the authors, from other related NMSOP-2 contributions, e.g., Fig. 4.11 from L. Küperkoch, Fig. 4.18 from S. Wendt, Fig. 4.20 from Th. Diehl, and Fig. 4.24 and Fig. 4.25 from M. Shinohara.

## 1 Aim

The exercise aims at:

- deepening the understanding and developing skills in using the related equations presented in section 4.1 of Chapter 4, Vol. 1;
- application of the conversion program **noisecon**, which can be downloaded by right mouse click on this program name in the NMSOP-2 content overview folder *Download Programs & Files.*;
- demonstrating that the various data presentations given in this Exercise and in Chapter 4 on signal and noise spectra or amplitudes in different kinematic units are in fact all compatible or – if not – that reasons for it can be given.

## 2 Fundamentals

The underlying fundamentals have been outlined in detail in the introduction to Chapter 4. In summary, the following should be remembered:

When a broadband signal is split up into narrower frequency bands with ideal band-pass filters, then

- the instantaneous amplitudes in the individual bands add up to the instantaneous amplitude of the broadband signal,
- the signal powers (or energies in case of *transient* signals) in the individual bands add up to the power (or energy) of the broadband signal,
- the RMS amplitudes in the individual bands DO NOT add up to the RMS amplitude of the broadband signal. The rms amplitude must be calculated from the total power.

**A specification of noise amplitudes without a definition of the bandwidth is meaningless!**

Also: Signal energy is the time-integral of power. Accordingly, transient signals have a finite energy while stationary (noise) signals have an infinite energy but a finite and, in the time average, constant power. Transient signals and stationary signals must therefore be treated differently. The spectrum of a transient signal cannot be expressed in the same units as the spectrum of a stationary signal. Earthquake spectra and noise spectra can, therefore, not be represented in the same plot, unless the conversion between the units is explained. Also, band-pass filtered amplitudes in different spectral ranges are comparable only when having been filtered with the same relative bandwidth (RBW). Note that in signal analysis the

"power" of a signal is understood to be the mean square of its instantaneous amplitude. Physical power is proportional but not identical to what is called "power" in signal analysis - for example, the electric power is  $W = U^2 / R$ , not  $W = U^2$ .

### 3 Data, relationships and programs

The exercises are based on data presented in Figs. 4.5 to 4.8 in Chapter 4, and the Figures 1 to 3 below.

FIG. 1. Vertical Earth motion amplitude spectral density.

**Figure 1** Compilation of various noise amplitude and power spectral densities at various stations and according to the Brune and Oliver (1959) noise model as published by Fix (1972).

**Figure 2** Cut-out section of a record of the WWSSN-LP seismograph of strong secondary ocean microseisms caused by a winter storm over the Atlantic ocean, reproduced at original scale (30 mm = 1 minute). The magnification at the dominant period is about 400 times.

**Figure 3** Output signal of an STS1 seismometer with the vacuum bell valve open (upper trace) and closed (lower trace), respectively. The noise in the top trace is caused by changes in barometric pressure.

For manual solutions use the respective relationships given in Eqs. (4.4) to (4.17) of Chapter 4 and a pocket calculator with the required basic functions. Alternatively, you may use the program **noisecon**.

## 4 Tasks

**Task 1:** Determine the relative bandwidth (RBW) of an

- a) 2-octave filter
- b) 2/3-octave filter
- c) 1/3-octave filter
- d) 1/6-decade filter

by using Eq. (4.15) in Chapter 4 and

- e) express the bandwidth of an 1/3-decade filter in terms of octaves

by using Eq. (4.17).

**Task 2:** Calculate for the noise maximum of the upper curve in Fig. 4.5 the corresponding RMS ground motion (velocity and displacement).

- a) Estimate the velocity power maximum from Fig. 4.5 (Note the logarithmic scale!).
- b) Give this value also in units of  $(\text{m/s})^2/\text{Hz}$ .
- c) Estimate the frequency  $f_0$  related to this maximum.
- d) Calculate the RMS-velocity amplitude  $a_{v\text{RMS}}$  by considering Eqs. (4.15) and (4.16) and a relative bandwidth of 2/3 octaves.
- e) Transform this RMS velocity amplitude determined under d) into the corresponding RMS displacement amplitude  $a_{d\text{RMS}}$  considering Eq. (4.4).

**Task 3:** Transform the displacement power values of Fig. 4.6 at  $f = 1 \text{ Hz}$  and  $f = 10 \text{ Hz}$  in

- a) units of  $\text{m}^2/\text{Hz}$ ,
- b) acceleration power values with units  $(\text{m/s}^2)^2/\text{Hz}$  using Eq. (4.5),
- c) the values determined under b) in units of dB referred to  $1 (\text{m/s}^2)^2/\text{Hz}$  according to Eq. 4.6) and
- d) compare the result with the respective values in Fig. 4.7 for the New Low Noise Model (NLNM).

**Task 4:** Determine from Fig. 4.7 the respective ground acceleration power spectral density values of the NHNM in units of  $(\text{nm/s}^2)^2/\text{Hz}$  for

a)  $f = 1 \text{ Hz}$  ,

b)  $f = 0.1 \text{ Hz}$  .

using Eq. (4.6)

**Task 5:** Select any period between 0.01 and 10,000 sec (e.g.,  $T = 100\text{s}$ ) and confirm that the presentations in Figs. 4.7 and 4.8 in Chapter 4 are equivalent when assuming a relative bandwidth of 1/6 decades as used in Fig. 4.8.

**Task 6:** Transform selected velocity PSD values given in the lower curve of Fig. 4.23 into acceleration PSD  $\mathbf{P}_a[\text{dB}] = 10 \log (\mathbf{P}_a / 1 \text{ (m/s}^2\text{)}^2/\text{Hz})$  via Eq. (4.5) and compare them with the NLNM at

a) 1.5 Hz and

b) 10 Hz.

**Task 7:** Figure 1 is a historical compilation of observed low noise spectra, now made obsolete by the USGS New Low Noise Model (NLNM).

- a) One of the two vertical scales has an incorrect label; both the name and the unit are incorrect. Try to correct it.
- b) Compare the lowermost curve (QC-AZ) to the NLNM, for example by plotting the points of the NLNM curve for 30 s, 300 s and 3000 s into the figure and discuss the difference.
- c) What would be the rms acceleration of the QC-AZ noise in a half-octave frequency band from 1 to (roughly) 1.4 Hz and in a half-octave period band from 25 to 35 seconds? Compare to figure 5.18 of the NLNM. Note that  $\frac{1}{2}$  octave and  $\frac{1}{6}$  decade are nearly the same.

**Task 8:** Assess the noise level of the microseism storm in Figure 2 with respect to the NLNM

- a) Determine the range of periods of the microseisms.
- b) Estimate the bandwidth of the microseisms, their center frequency  $f_0$  and RBW.
- c) Estimate the displacement  $a_{\text{RMS}}$  from the *average peak amplitudes* (which are about  $1.25a_{\text{RMS}}$ ). The magnification of the record is about 400 at  $f_0$ .
- d) Transform the displacement  $a_{\text{RMS}}$  into acceleration  $a_{\text{RMS}}$  and  $\mathbf{P}_a [\text{dB}]$ .
- e) Compare with Fig. 4.7 and discuss possible differences.

**Taks 9:** Compare the noise level for the acceleration records of an STS1 seismometer shown in Figure 3 and compare it with the NLNM. Note that  $1 \text{ gal} = 10^{-2} \text{ m/s}^2$ .

- Estimate  $a_{\text{RMS}}$  from the *average peak amplitudes* in Figure 3, upper trace.
- Estimate the upper limit of  $a_{\text{RMS}}$  for the lower trace in Figure 3.
- Estimate the periods and bandwidth of the noise in Figure 3.
- Compare the  $a_{\text{RMS}}$  for the upper and the lower trace with the NLNM presentation in Fig. 4.8.
- Discuss the differences.

## 5 Solutions

**Note:** The errors in eye readings of the required parameters from the diagrams may be 10 to 30 %. Therefore, it is acceptable if your solutions differ from the ones given below in the same order or by about 1 to 3 dB in power. In case of larger deviations check your readings and calculations. Also: all power values given below in dB relate to the respective units in Fig. 4.7.

- Task 1:**
- 1.5
  - 0.466
  - 0.231
  - 0.386
  - 1.1 octaves

- Task 2:**
- $7 \times 10^{-8} (\text{cm/s})^2/\text{Hz}$
  - $7 \times 10^{-12} (\text{m/s})^2/\text{Hz}$
  - 0.16 Hz
  - $a_{\text{vRMS}} \approx 7 \times 10^{-7} \text{ m/s}$
  - $a_{\text{dRMS}} \approx 7 \times 10^{-7} \text{ m}$

- Task 3:**
- $2 \times 10^{-18} \text{ m}^2/\text{Hz}$  at 1 Hz and  $1.5 \times 10^{-22} \text{ m}^2/\text{Hz}$  at 10 Hz
  - $3.12 \times 10^{-15} (\text{m/s}^2)^2/\text{Hz}$  at 1 Hz and  $2.3 \times 10^{-15} (\text{m/s}^2)^2/\text{Hz}$  at 10 Hz

c) - 145 dB for 1 Hz and -146 dB for 10 Hz

d) The noise power at this site is for the considered frequencies about 20 dB higher than for the NLNM.

**Task 4:** a) and b)  $\approx -117$  dB, i.e.,  $\approx 2 \times 10^6 \text{ (nm/s}^2\text{)}^2/\text{Hz}$  ;

**Task 5:** For  $T = 100$  s we get from Fig. 4.7  $\mathbf{P_a}$  [dB] = -185 dB. With  $\text{RBW} = 0.3861$  for 1/6 octave bandwidth and  $f = 0.01$  Hz we calculate with Eq. (4.16)  $a_{\text{RMS}}^2 = 1.1 \times 10^{-21} \text{ (m/s}^2\text{)}^2$  which is about -210 dB, in agreement with Fig. 4.8.

**Task 6:** a)  $\mathbf{P_a} \approx -153$  db, 16 dB above the NLNM

b)  $\mathbf{P_a} \approx -153$  db, 15 dB above the NLNM

**Task 7:**

a) The amplitude-density scale in Figure 1 is inapplicable to noise and cannot be related to the power-density scale, which is correct.

b) It is convenient to express the amplitudes in decibels relative to  $1 \text{ m}^2/\text{Hz}$ . For example,  $10^{-13} \text{ m}^2/\text{Hz}$  corresponds to -130 dB,  $2 \times 10^{-13} \text{ m}^2/\text{Hz}$  to -127 dB,  $5 \times 10^{-13} \text{ m}^2/\text{Hz}$  to -123 dB,  $10^{-12} \text{ m}^2/\text{Hz}$  to -120 dB. In these units we obtain:

At a period of 30 s, the NLNM is at -157 dB while QC-AZ is at -163 dB

At a period of 300 s, the NLNM is at -120 dB while QC-AZ is at -100 dB

At a period of 3000 s, the NLNM is at -59 dB while QC-AZ is at -17 dB

Obviously, the authors of figure 1 were able to resolve minimum ground noise at 30 s but not at much longer periods where their instruments were too noisy.

c) Half-octave band around 1.2 Hz (0.83 s): QC-AZ has a displacement power density of  $10^{-20} \text{ m}^2/\text{Hz}$ . Multiply by the fourth power of the angular frequency,  $2\pi \times 1.2$  Hz, to obtain the approximate power density of acceleration,  $3.2 \times 10^{-17} \text{ m}^2/\text{s}^4/\text{Hz}$ . Multiply with the bandwidth of 0.4 Hz to obtain the total power,  $1.3 \times 10^{-17} \text{ m}^2/\text{s}^4$ . Take the square root to obtain the rms amplitude,  $3.6 \times 10^{-9} \text{ m/s}^2$ . The power can also be expressed as  $10 \times \log(1.3 \times 10^{-17}) \text{ dB} = -169 \text{ dB}$  relative to  $1 \text{ m}^2/\text{s}^4$ . One would attribute the same number of decibels to the rms amplitude, understanding that decibels always refer to power. The NLNM has -172 dB.

For the half-octave band around 27 s (0.037 Hz), the bandwidth is 0.011 Hz and the rms acceleration  $4.2 \times 10^{-11} \text{ m/s}^2$ , which can also be expressed as -207 dB. The NLNM has -200 dB.

- Task 8:**
- a) The periods of the microseisms in Figure 2 vary between  $T = 7$  s (for the smaller amplitudes) and  $T = 10$  s (for the largest amplitudes).
  - b) From this upper and lower period follows with Eq. (4.13)  $n \approx 0.5$  octaves or  $m \approx 1/6$  decade, a center frequency of  $f_0 \approx 0.119$  Hz ( $T_0 \approx 8.4$  s) and an RBW of  $\approx 0.36$
  - c) Maximum double trace amplitudes of the microseisms range between about 6 and 3 mm, average about 4.5 mm, corresponding to a “true” *average peak ground amplitude* of about  $5.6 \times 10^{-6}$  m and thus to a displacement  $a_{\text{RMS}} \approx 4.5 \times 10^{-6}$  m.
  - d) The acceleration  $a_{\text{RMS}} \approx 2.5 \times 10^{-6}$  m for  $f_0 \approx 0.119$  Hz and  $P_a \approx -98$  dB.
  - e)  $P_a \approx -98$  dB for this microseismic storm is close to the power at the NHNM peak around  $T = 5$  s ( $-96.5$  dB) but about 15 dB higher than the NHNM values at  $T \approx 8$  s. Thus, the record corresponds to a really strong microseism storm.
- Task 9:**
- a) From Figure 3, upper trace, the estimated *average peak amplitude* is about  $2.5 \mu\text{gal}$  and thus  $a_{\text{RMS}}$  about  $2 \times 10^{-8}$  m/s<sup>2</sup>.
  - b) The related upper limit of about  $1/100^{\text{th}}$  of a), i.e.,  $a_{\text{RMS}} < 2 \times 10^{-10}$  m/s<sup>2</sup>.
  - c) The periods of the noise in Figure 3 range between roughly 180 s and 750 s. This corresponds to a bandwidth of about 2 octaves or an RBW of 1.5.
  - d) The  $a_{\text{RMS}}$  for the open valve corresponds to  $-154$  dB, that for the closed valve to  $< -194$  dB.
  - e) Taking into account that Fig. 4.8 was calculated for  $1/6$  decade bandwidth only but the bandwidth of the considered noise signals being about 3 times larger we have to assume an about 5 dB higher noise level in Fig. 4.8. Therefore, for periods  $< 30$  s the barometric pressure noise is surely well below the NLNM when the sensor operates in a vacuum. A higher resolution of the record with the vacuum bell valve closed would be required in order to determine the noise level distance to the NLNM for  $T > 30$  s.

## 5.1 Overview

There are two basic types of seismic sensors: inertial seismometers which measure ground motion relative to an inertial reference (a suspended mass), and strainmeters or extensometers which measure the motion of one point of the ground relative to another. Since the motion of the ground relative to an inertial reference is in most cases much larger than the differential motion within a vault of reasonable dimensions, inertial seismometers are generally more sensitive to earthquake signals. However, at very low frequencies it becomes increasingly difficult to maintain an inertial reference, and for the observation of low-order free oscillations of the Earth, tidal motions, and quasi-static deformations, strainmeters may outperform inertial seismometers. Strainmeters are conceptually simpler than inertial seismometers although their technical realization and installation may be more difficult (see IS 5.1). This Chapter is concerned with inertial seismometers only. For a more comprehensive description of inertial seismometers, recorders and communication equipment see Havskov and Alguacil (2002).

An inertial seismometer converts ground motion into an electric signal but its properties can not be described by a single scale factor, such as output volts per millimeter of ground motion. The response of a seismometer to ground motion depends not only on the amplitude of the ground motion (how large it is) but also on its time scale (how sudden it is). This is because the seismic mass has to be kept in place by a mechanical or electromagnetic restoring force. When the ground motion is slow, the mass will move with the rest of the instrument, and the output signal for a given ground motion will therefore be smaller. The system is thus a high-pass filter for the ground displacement. This must be taken into account when the ground motion is reconstructed from the recorded signal, and is the reason why we have to go to some length in discussing the dynamic transfer properties of seismometers.

The dynamic behavior of a seismograph system within its linear range can, like that of any linear time-invariant (LTI) system, be described with the same degree of completeness in four different ways: by a linear differential equation, the Laplace transfer function (5.2.2), the complex frequency response (5.2.3), or the impulse response of the system (5.2.4). The first two are usually obtained by a mathematical analysis of the physical system (the hardware). The latter two are directly related to certain calibration procedures (5.6.4 and 5.6.5) and can

therefore be determined from calibration experiments where the system is considered as a “black box”(this is sometimes called an identification procedure). However, since all four are mathematically equivalent, we can derive each of them either from a knowledge of the physical components of the system or from a calibration experiment. The mutual relations between the “time-domain” and “frequency-domain” representations are illustrated in Fig. 5.1. Practically, the mathematical description of a seismometer is limited to a certain bandwidth of frequencies that should at least include the bandwidth of seismic signals. Within this limit then any of the four representations describe the system's response to arbitrary input signals completely and unambiguously. The viewpoint from which they differ is how efficiently and accurately they can be implemented in different signal-processing procedures.

In digital signal processing, seismic sensors are often represented with other methods that are efficient and accurate but not mathematically exact, such as recursive (IIR) filters. Digital signal processing is however beyond the scope of this section. A wealth of textbooks is available both on analog and digital signal processing, for example Oppenheim and Willsky (1983) for analog processing, Oppenheim and Schaffer (1975) for digital processing, and Scherbaum (1996, 2007) for seismological applications.

The most commonly used description of a seismograph response in the classical observatory practice has been the “*magnification curve*”, i.e. the frequency-dependent magnification of the ground motion. Mathematically this is the modulus (absolute value) of the complex frequency response, usually called the *amplitude response*. It specifies the steady-state harmonic responsivity (amplification, magnification, conversion factor) of the seismograph as a function of frequency. However, for the correct interpretation of seismograms, also the phase response of the recording system must be known. It can in principle be calculated from the amplitude response, but is normally specified separately, or derived together with the amplitude response from the mathematically more elegant description of the system by its *complex transfer function* or its *complex frequency response*.

While for a purely electrical filter it is usually clear what the amplitude response is - a dimensionless factor by which the amplitude of a sinusoidal input signal is multiplied - the situation is not always as clear for seismometers because different authors may prefer to measure the input signal (the ground motion) in different ways: as a displacement, a velocity, or an acceleration. Both the physical dimension and the mathematical form of the transfer function depend on the definition of the input signal, and one must sometimes guess from the physical dimension to what sort of input signal it applies. The output signal, traditionally a needle deflection, is now normally a voltage, a current, or a number of counts.

Calibrating a seismograph means measuring (and in some cases adjusting) its transfer properties and expressing them as a complex frequency response or one of its mathematical equivalents. For most applications the result must be available as parameters of a mathematical formula, not as raw data; so determining parameters by fitting a theoretical curve of known shape to the data is usually part of the procedure. Practically, seismometers are calibrated in two steps.

The first step is an electrical calibration (5.6.1) in which the seismic mass is excited with an electromagnetic force. Most seismometers have a built-in calibration coil that can be connected to an external signal generator for this purpose. Usually the response of the system to different sinusoidal signals at frequencies across the system's passband (5.6.4), to impulses or steps (5.6.5), or to arbitrary broadband signals (5.6.6) is observed while the absolute

magnification or gain remains unknown. For the exact calibration of sensors with a large dynamic range such as those employed in modern seismograph systems, the latter method is most appropriate. Shake tables are not suitable to measure the response of a seismometer over a large bandwidth.

The second step, the determination of the absolute gain, is more difficult because it requires mechanical test equipment in all but the simplest cases (5.6.3). The most direct method is to calibrate the seismometer on a shake table (5.6.9) or step table (5.6.10). The frequency at which the absolute gain is measured must be chosen so as to minimize noise and systematic errors, and is often predetermined by these conditions within narrow limits. Other mechanical devices such as mechanical balances and machine tools can also provide a suitable mechanical input for an absolute calibration (5.6.10, 5.6.11).

## 5.2 Basic theory

This section introduces some basic concepts of the theory of linear systems. For a more complete and rigorous treatment, the reader should consult a textbook such as by Oppenheim and Willsky (1983). Digital signal processing is based on the same concepts but the mathematical formulations are different for discrete (sampled) signals (see Oppenheim and Schaffer, 1999, 2009; Scherbaum, 1996, 2007; Plešinger et al., 1996). Readers who are familiar with the mathematics may proceed to section 5.3.

### 5.2.1 The complex notation

A fundamental mathematical property of linear time-invariant (LTI) systems such as seismographs (as long as they are not driven out of their linear operating range) is that they do not change the waveform of sinewaves and of exponentially decaying or growing sinewaves. A more abstract mathematical formulation of this statement is that these waveforms are eigenfunctions of the differential operators describing LTI systems. An input signal of the form

$$f(t) = e^{\sigma t} (a_1 \cos \omega t + b_1 \sin \omega t) \quad (5.1)$$

will produce an output signal

$$g(t) = e^{\sigma t} (a_2 \cdot \cos \omega t + b_2 \cdot \sin \omega t) \quad (5.2)$$

with the same  $\sigma$  and  $\omega$ . Note that  $\omega$  is the angular frequency, which is  $2\pi$  times the common frequency. Using Euler's identity

$$e^{j\omega t} = \cos \omega t + j \sin \omega t \quad (5.3)$$

and the rules of complex algebra, we may write our input and output signals as

$$f(t) = \Re[c_1 \cdot e^{(\sigma + j\omega)t}] \text{ and } g(t) = \Re[c_2 \cdot e^{(\sigma + j\omega)t}] \quad (5.4)$$

respectively, where  $\Re[.]$  denotes the real part and  $c_1 = a_1 - jb_1$ ,  $c_2 = a_2 - jb_2$  are complex amplitudes. It can now be seen that the only difference between the input and output signal lies in the amplitude, not in the waveform. The ratio  $c_2 / c_1$  is the complex gain of the system, and for  $\sigma = 0$ , it is the value of the complex frequency response at the angular frequency  $\omega$ . What we have outlined here may be called the engineering approach to complex notation. The sign  $\Re[.]$  for the real part is often omitted but always understood.

The mathematical approach is slightly different in that real signals are not considered to be the real parts of complex signals but the sum of two complex-conjugate signals with positive and negative frequencies:

$$f(t) = c_1 \cdot e^{(\sigma + j\omega)t} + c_1^* \cdot e^{(\sigma - j\omega)t} \quad (5.5)$$

where the asterisk  $*$  denotes the complex conjugate. The mathematical notation is slightly less concise, but since for real signals only the term with  $c_1$  must be explicitly written down (the other one being its complex conjugate), the two notations become very similar. However, the  $c_1$  term describes the whole signal in the engineering convention but only half of the signal in the mathematical notation! This may easily cause confusion, especially in the definition of power spectra. Power spectra computed after the engineer's method (such as the USGS Low Noise Model, see 5.5.1 and Chapter 4) attribute all power to positive frequencies and therefore have twice the power appearing in the mathematical notation.

## 5.2.2 The Laplace transformation

A signal that has a definite beginning in time (such as the seismic waves from an earthquake) can be decomposed into exponentially growing, stationary, or exponentially decaying sinusoidal signals with the *Laplace integral transformation*:

$$f(t) = \frac{1}{2\pi j} \int_{\sigma - j\infty}^{\sigma + j\infty} F(s) e^{st} ds, \quad F(s) = \int_0^\infty f(t) e^{-st} dt. \quad (5.6)$$

The first integral defines the inverse transformation (the synthesis of the given signal) and the second integral the forward transformation (the analysis). It is assumed here that the signal begins at or after the time origin.  $s$  is a complex variable that may assume any value for which the second integral converges; depending on  $f(t)$ , it may not converge when  $s$  has a negative real part. The Laplace transform  $F(s)$  is then said to “exist” for this value of  $s$ . The real parameter  $\sigma$  which defines the path of integration for the inverse transformation (the first integral) can be arbitrarily chosen as long as the path remains on the right side of all singularities of  $F(s)$  in the complex  $s$  plane. This parameter decides whether  $f(t)$  is synthesized from decaying ( $\sigma < 0$ ), stationary ( $\sigma = 0$ ) or growing ( $\sigma > 0$ ) sinusoids. Remember that the mathematical expression  $e^{st}$  with complex  $s$  represents a growing or decaying sinewave, and with imaginary  $s$  a pure sinewave.

The time derivative  $\dot{f}(t)$  has the Laplace transform  $s \cdot F(s)$ , the second derivative  $\ddot{f}(t)$  has  $s^2 \cdot F(s)$ , etc. Suppose now that an analog data-acquisition or data-processing system is characterized by the linear differential equation

$$c_2 \ddot{f}(t) + c_1 \dot{f}(t) + c_0 f(t) = d_2 \ddot{g}(t) + d_1 \dot{g}(t) + d_0 g(t) \quad (5.7)$$

where  $f(t)$  is the input signal,  $g(t)$  is the output signal, and the  $c_i$  and  $d_i$  are constants. We may then subject each term in the equation to a Laplace transformation and obtain

$$c_2 s^2 F(s) + c_1 s F(s) + c_0 F(s) = d_2 s^2 G(s) + d_1 s G(s) + d_0 G(s) \quad (5.8)$$

from which we get

$$G(s) = \frac{c_2 s^2 + c_1 s + c_0}{d_2 s^2 + d_1 s + d_0} F(s) \quad (5.9)$$

We have thus expressed the Laplace transform of the output signal by the Laplace transform of the input signal, multiplied by a known rational function of  $s$ . From this we obtain the output signal itself by an inverse Laplace transformation. This means, we can solve the differential equation by transforming it into an algebraic equation for the Laplace transforms. Of course, this is only practical if we are able to evaluate the integrals analytically, which is the case for a wide range of “mathematical” signals. Real signals must be approximated by suitable mathematical functions for a transformation. The method can obviously be applied to linear and time-invariant differential equations of any order. (Time-invariant means that the properties of the system, and hence the coefficients of the differential equation, do not depend on time.)

The rational function

$$H(s) = \frac{c_2 s^2 + c_1 s + c_0}{d_2 s^2 + d_1 s + d_0} \quad (5.10)$$

is the (Laplace) transfer function of the system described by the differential equation (5.7). It contains the same information on the system as the differential equation itself.

Generally, the transfer function  $H(s)$  of an LTI system is the complex function for which

$$G(s) = H(s) \cdot F(s) \quad (5.11)$$

with  $F(s)$  and  $G(s)$  representing the Laplace transforms of the input and output signals.

A rational function like  $H(s)$  in (5.10), and thus an LTU system, can be characterized up to a constant factor by its poles and zeros. This is discussed in section 5.2.6.

### 5.2.3 The Fourier transformation

Somewhat closer to intuitive understanding but mathematically less general than the Laplace transformation is the Fourier transformation

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{F}(\omega) e^{j\omega t} d\omega, \quad \tilde{F}(\omega) = \int_{-\infty}^{\infty} f(t) e^{-j\omega t} dt \quad (5.12)$$

The signal is here assumed to have a finite energy so that the integrals converge. The condition that no signal is present at negative times can be dropped in this case. The Fourier transformation decomposes the signal into purely harmonic (sinusoidal) waves  $e^{j\omega t}$ . The direct and inverse Fourier transformation are also known as a harmonic analysis and synthesis.

Although the mathematical concepts behind the Fourier and Laplace transformations are different, we may consider the Fourier transformation as a special version of the Laplace transformation for real frequencies, i.e. for  $s = j\omega$ . In fact, by comparison with Eq. (5.6), we see that  $\tilde{F}(\omega) = F(j\omega)$ , i.e. the Fourier transform for real angular frequencies  $\omega$  is identical to the Laplace transform for imaginary  $s = j\omega$ . For practical purposes the two transformations are thus nearly equivalent, and many of the relationships between time signals and their transforms (such as the convolution theorem) are similar or the same for both. The function  $\tilde{F}(\omega)$  is called the complex frequency response of the system. Some authors use the name “transfer function” for  $\tilde{F}(\omega)$  as well; however,  $\tilde{F}(\omega) = F(j\omega)$  is not the same function as  $F(\omega)$ , so a different name are appropriate. The distinction between  $\tilde{F}(\omega)$  and  $F(s)$  is essential when systems are characterized by their poles and zeros. These are equivalent but not identical in the complex  $s$  and  $\omega$  planes, and it is important to know whether the Laplace or Fourier transform is meant. Usually, poles and zeros are given for the Laplace transform. In case of doubt, check the symmetry of the poles and zeros in the complex plane: those of the Laplace transform are symmetric to the real axis as in Figure 1 of exercise EX 5.7 while those of the Fourier transform are symmetric to the imaginary axis.

The absolute value  $|\tilde{F}(\omega)|$  is called the amplitude response, and the phase of  $\tilde{F}(\omega)$  the phase response of the system. Note that amplitude and phase do not form a symmetric pair; however a certain mathematical symmetry (expressed by the Hilbert transformation) exists between the real and imaginary parts of a rational transfer function, and between the phase response and the natural logarithm of the amplitude response.

The definition of the Fourier transformation according to Eq. (5.12) applies to continuous transient signals. For other mathematical representations of a signal, different definitions must be used:

$$f(t) = \sum_{v=-\infty}^{\infty} b_v e^{2\pi j v t / T}, \quad b_v = \frac{1}{T} \int_0^T f(t) e^{-2\pi j v t / T} dt \quad (5.13)$$

for periodic signals  $f(t)$  with a period  $T$ , and

$$f_k = \frac{1}{M} \sum_{l=0}^{M-1} c_l e^{2\pi j k l / M}, \quad c_l = \sum_{k=0}^{M-1} f_k e^{-2\pi j k l / M} \quad (5.14)$$

for time series  $f_k$  consisting of  $M$  equidistant samples (such as digital seismic data). We have written the inverse transform (the synthesis) first in each case. The successive approximation of arbitrary signals by sums of sine waves is demonstrated in the **fourierdemo** program (section 5.8).

The Fourier integral transformation (Eq. 5.12) is mainly an analytical tool; the integrals are not normally evaluated numerically because the discrete Fourier transformation (Eq. 5.14) permits more efficient computations. Eq. (5.13) is the Fourier series expansion of periodic functions, also mainly an analytical tool but also useful to represent periodic test signals. The discrete Fourier transformation (Eq. 5.13) is sometimes considered as being a discretized, approximate version of Eqs. (5.12) or (5.14) but is actually a mathematical tool in its own right: it is a mathematical identity that does not depend on any assumptions on the series  $f_k$ . Its relationship with the other two transformations, and especially the interpretation of the subscript  $l$  as representing a single frequency, do however depend on the properties of the original, continuous signal. The most important condition is that the bandwidth of the signal before sampling must be limited to less than half of the sampling rate  $f_s$ ; otherwise the sampled series will not contain the same information as the original. The bandwidth limit  $f_n = f_s/2$  is called the *Nyquist frequency*. Whether we consider a signal as periodic or as having a finite duration (and thus a finite energy) is to some degree arbitrary since we can analyze real signals only for finite intervals of time, and it is then a matter of definition whether we assume the signal to have a periodic continuation outside the interval or not.

The Fast Fourier Transformation or FFT (Cooley and Tukey, 1965) is a recursive algorithm to compute the sums in Eq. (5.14) efficiently, and does not constitute a mathematically different definition of the discrete Fourier transformation.

### 5.2.4 The impulse response

A useful (although mathematically difficult) fiction is the Dirac “needle” pulse  $\delta(t)$  (e.g. Oppenheim and Willsky, 1983), supposed to be an infinitely short, infinitely high, positive pulse at the time origin whose integral over time equals 1. It can not be realized, but its time-integral, the unit step function, can be approximated by switching a current on or off or by suddenly applying or removing a force. According to the definitions of the Laplace and Fourier transforms, both transforms of the Dirac pulse have the constant value 1. The amplitude spectrum of the Dirac pulse is “white”, this means, it contains all frequencies with equal amplitude. In this case Eq. (5.11) reduces to  $G(s)=H(s)$ . The transfer function  $H(s)$  is thus the Laplace transform of the impulse response  $g(t)$ . Likewise, the complex frequency response is the Fourier transform of the impulse response. All information contained in these complex functions is also contained in the impulse response of the system. The same is true for the step response, which is often used to test or calibrate seismic equipment.

Explicit expressions for the response of a linear system to impulses, steps, ramps and other simple waveforms can be obtained by evaluating the inverse Laplace transform over a suitable contour in the complex  $s$  plane, provided that the poles and zeros are known. The result, generally a sum of decaying complex exponential functions (sinusoids), can then be

numerically evaluated with a computer or even a calculator. Although this is an elegant way of computing the response of a linear system to simple input signals with any desired precision, a warning is necessary: the numerical samples so obtained are not the same as the samples obtained with a digitizer. The digitizer must limit the bandwidth before sampling and therefore does not generate instantaneous samples but some sort of time-averages. For computing samples of band-limited signals, different mathematical concepts must be used (Schuessler, 1981).

Specifying the impulse or step response of a system in place of its transfer function is not practical because the analytic expressions are cumbersome to write down and represent signals of infinite duration that can not be tabulated in full length.

### 5.2.5 The convolution theorem

Any signal may be understood as consisting of a sequence of pulses. This is obvious in the case of sampled signals, but can be generalized to continuous signals by representing the signal as a continuous sequence of Dirac pulses. We may construct the response of a linear system to an arbitrary input signal as a sum over suitably delayed and scaled impulse responses. This process is called a convolution:

$$g(t) = \int_0^{\infty} h(t') f(t-t') dt' = \int_0^{\infty} h(t-t') f(t') dt' \quad (5.15)$$

Here  $f(t)$  is the input signal and  $g(t)$  the output signal while  $h(t)$  characterizes the system. We assume that the signals are causal (i.e. zero at negative time), otherwise the integration would have to start at  $-\infty$ . Taking  $f(t) = \delta(t)$ , i.e. using a single impulse as the input, we get

$$g(t) = \int h(t') \delta(t-t') dt' = h(t),$$

so  $h(t)$  is in fact the impulse response of the system.

The response of a linear system to an arbitrary input signal can thus be computed either by convolution of the input signal with the impulse response in time domain, or by multiplication of the Laplace-transformed input signal with the transfer function, or by multiplication of the Fourier-transformed input signal with the complex frequency response in frequency domain.

Since instrument responses are often specified as a function of frequency, the FFT algorithm has become a standard tool to compute output signals. The FFT method assumes, however, that all signals are periodic, and is therefore mathematically inaccurate when this is not the case. Signals must in general be tapered to avoid spurious results. (A taper is a weight function that is zero or small at the beginning and end of the time interval). Fig. 5.1 illustrates the interrelations between signal processing in the time and frequency domains.

**Fig. 5.1** Pathways of signal processing in the time and frequency domains. The asterisk between  $h(t)$  and  $f(t)$  indicates a convolution. An interactive version of this scheme with a number of test signals is available as a BASIC program **filtdemo** (section 5.8). Since the complex frequency response of a layered elastic medium can be expressed by a mathematical formula, this scheme can also be used for computation of synthetic seismograms.

In digital processing, these methods translate into convolving discrete time series or transforming them with the FFT method and multiplying the transforms. For impulse responses with more than 100 samples, the FFT method is usually more efficient. The convolution method is also known as a FIR (finite impulse response) filtration. A third method, the recursive or IIR (infinite impulse response) filtration (e.g. Oppenheim and Schaffer, 2009) is often preferred for its flexibility and efficiency. The design of IIR filters requires special attention because for mathematical reasons they cannot exactly represent rational transfer functions (see the remarks under 5.6.6).

### 5.2.6 Specifying a system

When  $P(s)$  is a polynomial of  $s$  and  $\alpha$  is a specific value of  $s$  for which  $P(\alpha) = 0$ , then  $\alpha$  is called a zero, or a root, of the polynomial. A polynomial of order  $n$  has  $n$  complex zeros  $\alpha_i$ , and can be factorized as  $P(s) = p \cdot \prod (s - s_i)$ . Thus, the zeros of a polynomial together with the constant  $p$  determine the polynomial completely. Since our transfer functions  $H(s)$  are the ratio of two polynomials as in Eq. (5.10), they can be specified by their zeros (the zeros of the numerator  $G(s)$ ), their poles (the zeros of the denominator  $F(s)$ ), and a gain factor (or equivalently the total gain at a given frequency). The whole system, as long as it remains in its linear operating range and does not produce noise, can thus be described by a small number of discrete parameters.

Transfer functions are usually specified according to one of the following concepts:

1. The real coefficients of the polynomials in the numerator and denominator are listed.
2. The denominator polynomial is decomposed into normalized first-order and second-order factors with real coefficients (a total decomposition into first-order factors would require complex coefficients). The factors can in general be attributed to individual modules of the system. They are preferably given in a form from which corner periods and damping coefficients can be read, as in Eqs. (5.23) to (5.25). The numerator often reduces to a gain factor times a power of  $s$ .

3. The poles and zeros of the transfer function are listed together with a gain factor. Poles and zeros must either be real or symmetric to the real axis, as mentioned above. When the numerator polynomial is  $s^m$ , then  $s = 0$  is an  $m$ -fold zero of the transfer function, and the system is a high-pass filter of order  $m$ . (Zeros at nonzero frequency do normally not appear in the transfer function of broadband seismographs because, if they occur mathematically, their effect must practically be cancelled by nearby poles; otherwise the response would not be called broadband.) Depending on the order  $n$  of the denominator and accordingly on the number of poles, the response may be flat at high frequencies ( $n = m$ ), or the system may act as a low-pass filter there ( $n > m$ ). The case  $n < m$  can occur only as an approximation in a limited bandwidth because no practical system can have an unlimited gain at high frequencies.

In the header of the widely used SEED-format data (10.4), the gain factor is split up into a normalization factor bringing the gain to unity at a specified normalization frequency in the passband of the system, and a gain factor representing the actual gain at this frequency. Text versions of dataless SEED headers, named response files or RESP files, can be downloaded for a large number of seismic stations from the IRIS Data Management Center: <http://www.iris.edu/dms/mda.htm>. EX\_5.5 contains an exercise in determining the response from given poles and zeros. An interactive, tutorial program **polzero** in BASIC is available for this purpose (section 5.8). RESP files are normally evaluated under LINUX with the EVALRESP software offered by the IRIS Data Management Center. The first section of a RESP file that describes the seismometer can also be interpreted in a MS-DOS environment with the **winresp** program (section 5.8, **polzero** folder). See also the exercises and worksheets mentioned at the end of section 5.2.

### 5.2.7 The mechanical pendulum

The simplest physical model for an inertial seismometer is a mass-and-spring system with viscous damping (Fig. 5.2).

We assume that the seismic mass is constrained to move along a straight line without rotation (i.e., it performs a pure translation). The mechanical elements are a mass of  $M$  kilograms, a spring with a stiffness  $S$  (measured in Newtons per meter), and a damping element with a constant of viscous friction  $D$  (in Newtons per meter per second). Let the time-dependent ground motion be  $x(t)$ , the absolute motion of the mass  $y(t)$ , and its motion relative to the ground  $z(t) = y(t) - x(t)$ . An acceleration  $\ddot{y}(t)$  of the mass results from any external force  $f(t)$  acting on the mass, and from the forces transmitted by the spring and the damper:

$$M \ddot{y}(t) = f(t) - S z(t) - D \dot{z}(t). \quad (5.16)$$

Since we are interested in the relationship between  $z(t)$  and  $x(t)$ , we rearrange this into

$$M \ddot{z}(t) + D \dot{z}(t) + S z(t) = f(t) - M \ddot{x}(t). \quad (5.17)$$

We observe that an acceleration  $\ddot{x}(t)$  of the ground has the same effect as an external force of magnitude  $f(t) = -M \ddot{x}(t)$  acting on the mass in the absence of ground acceleration. We may thus simulate a ground motion  $x(t)$  by applying a force  $-M \ddot{x}(t)$  to the mass while the

ground is not moving. The force is normally generated by sending a current through an electromagnetic transducer, but it may also be applied mechanically.

**Fig. 5.2** Elements of a mechanical harmonic oscillator.

### 5.2.8 Transfer functions of pendulums and electromagnetic seismometers

According to Eqs. (5.7) and (5.8), Eq. (5.17) can be rewritten as

$$(s^2 M + sD + S) Z = F - s^2 M X \quad (5.18)$$

or

$$Z = (F / M - s^2 X) / (s^2 + sD / M + S / M). \quad (5.19)$$

From this we can obtain directly the transfer functions  $T_f = Z/F$  for the external force  $F$  and  $T_d = Z/X$  for the ground displacement  $X$ . We arrive at the same result, expressed by the Fourier-transformed quantities, by simply assuming a time-harmonic motion  $x(t) = \tilde{X}e^{j\omega t} / 2\pi$  as well as a time-harmonic external force  $f(t) = \tilde{F}e^{j\omega t} / 2\pi$ , for which Eq. (5.17) reduces to

$$(-\omega^2 M + j\omega R + S)\tilde{Z} = \tilde{F} + \omega^2 M\tilde{X} \quad (5.20)$$

or

$$\tilde{Z} = (\tilde{F} / M + \omega^2 \tilde{X}) / (-\omega^2 + j\omega R / M + S / M). \quad (5.21)$$

While in mathematical derivations it is convenient to use the angular frequency  $\omega = 2\pi f$  to characterize a sinusoidal signal of frequency  $f$ , and some authors omit the word „angular“ in this context, we reserve the term „frequency“ to the number of cycles per second.

By checking the behavior of  $\tilde{Z}(\omega)$  in the limit of low and high frequencies, we find that the mass-and-spring system is a second-order high-pass filter for displacements and a second-order low-pass filter for accelerations and external forces (see Fig. 5.3). Its corner frequency is  $f_0 = \omega_0 / 2\pi$  with  $\omega_0 = \sqrt{S / M}$ . This is at the same time the „eigenfrequency“ or „natural frequency“ with which the mass oscillates when the damping is negligible. At the angular frequency  $\omega_0$ , the ground motion  $\tilde{X}$  is amplified by a factor  $\omega_0 M / R$  and phase shifted by

$\pi/2$ . The imaginary term in the denominator is usually written as  $2j\omega\omega_0h$  where  $h = D/(2\omega_0M)$  is the numerical damping, i.e., the ratio of the actual to the critical damping.

In order to convert the motion of the mass into an electric signal, the mechanical pendulum in the simplest case is equipped with an electromagnetic velocity transducer (see 5.3.8) whose output voltage we denote with  $\tilde{U}$ . We then have an electromagnetic seismometer (or geophone when designed for seismic exploration). When the responsivity of the transducer is  $E$  (volts per meter per second;  $\tilde{U} = -Ej\omega\tilde{Z}$ ) we get

$$\tilde{U} = -j\omega E(\tilde{F}/M + \omega^2\tilde{X})/(-\omega^2 + 2j\omega\omega_0h + \omega_0^2) \quad (5.22)$$

from which, in the absence of an external force (i.e.  $f(t) = 0$ ,  $\tilde{F} = 0$ ), we obtain the frequency-dependent complex response functions

$$\tilde{H}_d(\omega) := \tilde{U}/\tilde{X} = -j\omega^3 E/(-\omega^2 + 2j\omega\omega_0h + \omega_0^2) \quad (5.23)$$

for the displacement,

$$\tilde{H}_v(\omega) := \tilde{U}/(j\omega\tilde{X}) = -\omega^2 E/(-\omega^2 + 2j\omega\omega_0h + \omega_0^2) \quad (5.24)$$

for the velocity, and

$$\tilde{H}_a(\omega) := \tilde{U}/(-\omega^2\tilde{X}) = j\omega E/(-\omega^2 + 2j\omega\omega_0h + \omega_0^2) \quad (5.25)$$

for the acceleration.

With respect to its frequency-dependent response, the electromagnetic seismometer is a second-order high-pass filter for the velocity, and a band-pass filter for the acceleration. Its response to displacement has no flat part and no concise name. These responses (or, more precisely speaking, the corresponding amplitude responses) are illustrated in Fig. 5.3.

The mathematical and graphical representation of the response is the subject of several exercises and information sheets in this manual. EX 5.5 requires different mathematical descriptions of a broadband seismograph and EX 5.6 derives such descriptions for the now historical WWSSN-LP seismograph. IS 5.2 and EX 5.1 by J. Bribach explain the construction of Bode diagrams, a standardized asymptotic representation of the amplitude response.

**Fig. 5.3** Response curves of a mechanical seismometer (spring pendulum, left) and electrodynamic seismometer (geophone, right) with respect to different kinds of input signals (displacement, velocity and acceleration). The normalized frequency is the signal frequency divided by the eigenfrequency (corner frequency) of the seismometer. All of these response curves have a second-order corner at the normalized frequency 1. Step responses of second-order high-pass, band-pass and low-pass filters are shown in Fig. 5.23.

## 5.3 Design of seismic sensors

Although the mass-and-spring system of Fig. 5.2 is a useful mathematical model for a seismometer, it is incomplete as a practical design. The suspension must suppress five out of the six degrees of freedom of the seismic mass (three translational and three rotational) but the mass must still move as freely as possible in the remaining direction. This section discusses some of the mechanical concepts by which this can be achieved. In principle it is also possible to let the mass move in all directions and observe its motion with three orthogonally arranged transducers, thus creating a three-component sensor with only one suspended mass. Indeed, some historical instruments have made use of this concept. However, it is difficult to minimize the restoring force and to suppress parasitic rotations of the mass when its translational motion is unconstrained. Modern three-component seismometers therefore have separate mechanical sensors for the three axes of motion.

### 5.3.1 Pendulum-type seismometers

Most seismometers are of the pendulum type, i.e., they let the mass rotate around an axis rather than move along a straight line (Fig. 5.4 to Fig. 5.7). The point bearings in our figures are for illustration only; most seismometers have crossed flexural hinges. Pendulums are not only sensitive to translational but also to angular acceleration. Forbriger (2009) shows however that this sensitivity depends on an arbitrary definition. In order to decompose the motion of the pendulum into a translational and a rotational part, we must define an axis of rotation. When it is properly chosen, the rotational sensitivity disappears. The rotational component of seismic signals is however normally so small that there is no practical difference between linear-motion and pendulum-type seismometers.

**Fig. 5.4** (a) Garden-gate suspension; (b) Inverted pendulum.

For small translational ground motions the equation of motion of a pendulum is formally identical to Eq. (5.17) but  $z$  must then be interpreted as the angle of rotation. Since the rotational counterparts of the constants  $M$ ,  $D$ , and  $S$  in Eq. (5.17) are of little interest in modern electronic seismometers, we will not discuss them further and refer the reader instead to the older literature, such as Berlage (1932) or Willmore (1979).

The simplest example of a pendulum is a mass suspended with a string or wire (like Foucault's pendulum). When the mass has small dimensions compared to the length  $\ell$  of the string so that it can be idealized as a point mass, then the arrangement is called a

mathematical pendulum. Its period of oscillation is  $T = 2\pi\sqrt{\ell/g}$  where  $g$  is the gravitational acceleration. A mathematical pendulum of 1 m length has a period of nearly 2 seconds; for a period of 20 seconds the length has to be 100 m. Clearly, this is not a suitable design for a long-period seismometer.

### 5.3.2 Decreasing the restoring force

At low frequencies and in the absence of an external force, Eq. (5.17) can be simplified to  $Sz = -M\ddot{x}$  and read as follows: A relative displacement  $-\Delta z$  of the seismic mass indicates a ground acceleration

$$\ddot{x} = (S/M) \Delta z = \omega_0^2 \Delta z = (2\pi/T_0)^2 \Delta z \quad (5.26)$$

where  $\omega_0$  is the angular eigenfrequency of the pendulum, and  $T_0$  its eigenperiod. If  $\Delta z$  is the smallest mechanical displacement that can be measured electronically, then the formula determines the smallest ground acceleration that can be observed at low frequencies. For a given transducer, it is inversely proportional to the square of the free period of the suspension. A sensitive long-period seismometer therefore requires either a pendulum with a low eigenfrequency or a very sensitive transducer. Since the eigenfrequency of an ordinary pendulum is essentially determined by its size, and seismometers must be reasonably small, astatic suspensions have been invented that combine small overall size with a long free period.

The simplest astatic suspension is the “garden-gate” pendulum used in horizontal seismometers (Fig. 5.4a). The mass moves in a nearly horizontal plane around a nearly vertical axis. Its free period is the same as that of a mass suspended from the point where the plumb line through the mass intersects the axis of rotation (Fig. 5.5a). The eigenperiod  $T_0 = 2\pi\sqrt{\ell/g \sin \alpha}$  is infinite when the axis of rotation is vertical ( $\alpha = 0$ ), and is usually adjusted by tilting the whole instrument. This is one of the earliest designs for long-period horizontal seismometers. Another early design is the inverted pendulum held in stable equilibrium by springs or by a stiff hinge (Fig. 5.4b); a famous example is Wiechert's horizontal pendulum built around 1905.

An astatic spring geometry for vertical seismometers invented by LaCoste (1934) is shown in Fig. 5.6a. The mass is in neutral equilibrium and has therefore an infinite free period when three conditions are met: the spring is pre-stressed to zero length (i.e. the spring force is proportional to the total length of the spring), its end points are seen under a right angle from the hinge, and the mass is balanced in the horizontal position of the boom. A finite free period is obtained by making the angle of the spring slightly smaller than  $90^\circ$ , or by tilting the frame accordingly. By simply rotating the pendulum, astatic suspensions with a horizontal or oblique (Fig. 5.6b) axis of sensitivity can be constructed as well.

**Fig. 5.5** Equivalence between a tilted “garden-gate” pendulum and a string pendulum. For a free period of 20 s, the string pendulum must be 100 m long. The tilt angle  $\alpha$  of a garden-gate pendulum with the same free period and a length of 30 cm is about  $0.2^\circ$ . The longer the period is made, the less stable it will be under the influence of small tilt changes. (b) Period-lengthening with an auxiliary compressed spring.

**Fig. 5.6** LaCoste suspensions.

The astatic leaf-spring suspension (Fig. 5.7a, Wielandt, 1975), in a limited range around its equilibrium position, is comparable to a LaCoste suspension but is much simpler to manufacture. A similar spring geometry is used in the triaxial seismometer Streckeisen STS2 (Fig. 5.7b, DS 5.1 and Wielandt and Streckeisen, 1982). The delicate equilibrium of forces in astatic suspensions makes them susceptible to external disturbances such as changes in temperature; they are difficult to operate without a stabilizing feedback system.

**Fig. 5.7** Leaf-spring astatic suspensions.

Apart from genuinely astatic designs, almost any seismic suspension can be made astatic with an auxiliary spring acting normal to the line of motion of the mass and pushing the mass away from its equilibrium (Fig. 5.5b). The long-period performance of such suspensions, however, is quite limited. Neither the restoring force of the original suspension nor the destabilizing force of the auxiliary spring can be made perfectly linear (i.e. proportional to the displacement). While the linear components of the force may cancel, the nonlinear terms remain and cause the oscillation to become non-harmonic and even unstable at large amplitudes. Viscous and hysteretic behavior of the springs may also cause problems. The additional spring (which has to be soft) may introduce parasitic resonances. Modern seismometers do not use this concept and rely either on a genuinely astatic spring geometry or on the sensitivity of electronic transducers.

### 5.3.3 Sensitivity of horizontal seismometers to tilt

We have already seen (Eq. (5.17)) that a seismic acceleration of the ground has the same effect on the seismic mass as an external force. The largest such force is gravity. It is normally cancelled by the suspension, but when the seismometer is tilted, the projection of the vector of gravity onto the axis of sensitivity changes, producing a force that is in most cases undistinguishable from a seismic signal (Fig. 5.8).

**Fig. 5.8** The relative motion of the seismic mass is the same when the ground is accelerated to the left as when it is tilted to the right.

Undesired tilt at seismic frequencies may be caused by moving or variable surface loads such as cars, people, and atmospheric pressure. The resulting disturbances are a second-order effect in well-adjusted vertical seismometers but otherwise a first-order effect (see Rodgers, 1968; Rodgers, 1969). This explains why horizontal long-period seismic traces are always noisier than vertical ones. A short, impulsive tilt excursion is equivalent to a step-like change of ground velocity and therefore will cause a long-period transient in a horizontal broadband seismometer. For periodic signals, the apparent horizontal displacement associated with a given tilt increases with the square of the period. At tidal and lower frequencies, all horizontal seismometers act as tiltmeters.

Fig. 5.9 illustrates the effect of barometrically induced ground tilt. Let us assume that the ground is vertically deformed by as little  $\pm 1 \mu\text{m}$  over a distance of 3 km, and that this deformation oscillates with a period of 10 minutes. A simple calculation then shows that seismometers A and C see a vertical acceleration of  $\pm 10^{-10} \text{ m/s}^2$  while B sees a horizontal acceleration of  $\pm 10^{-8} \text{ m/s}^2$ . The horizontal noise is thus 100 times larger than the vertical one. In absolute terms, even the vertical acceleration is by a factor of four above the minimum ground noise in one octave as specified by the USGS Low Noise Model (see 5.5.1)

**Fig. 5.9** Ground tilt caused by the atmospheric pressure is the main source of very-long-period noise on horizontal seismographs.

### 5.3.4 Direct effects of barometric pressure

Besides tilting the ground, the continuously fluctuating barometric pressure affects seismometers in at least three different ways: (1) when the seismometer is not enclosed in a hermetic housing, the mass will experience a variable buoyancy which can cause large disturbances in vertical sensors; (2) changes of pressure also produce adiabatic changes of temperature which affect the suspension (see the next subsection). Both effects can be greatly reduced by making the housing airtight or installing the sensor inside an external pressure jacket; however, then (3) the housing or jacket may be deformed by the pressure and these deformations may be transmitted to the seismic suspension as stress or tilt. While it is always worthwhile to protect vertical long-period seismometers from changes of the barometric pressure, it has often been found that horizontal long-period seismometers are less sensitive to barometric noise when they are not hermetically sealed. This, however, may cause other problems such as corrosion.

### 5.3.5 Effects of temperature

The equilibrium between gravity and the spring force in a vertical seismometer is disturbed when the temperature changes. Although thermally self-compensated alloys are available for springs, such a spring does not make a compensated seismometer. The geometry of the whole suspension changes with temperature; the seismometer must therefore be compensated as a whole. However, the different time constants involved prevent an efficient compensation at seismic frequencies. Short-term changes of temperature, therefore, must be suppressed by the combination of thermal insulation and thermal inertia. Special caution is required with seismometers where electronic components are enclosed with the mechanical sensor: these instruments heat themselves up when insulated and are then very sensitive to air drafts, so the insulation must at the same time suppress any possible air convection (5.5.3). Long-term (seasonal) changes of temperature do not interfere with the seismic signal (except when they cause convection in the vault) but may drive the seismic mass out of its operating range. Eq. (5.26) can be used to calculate the thermal drift of a vertical seismometer when the temperature coefficient of the spring force is formally assigned to the gravitational acceleration.

### 5.3.6 Sensitivity to magnetic fields

Broadband seismometers are to some degree sensitive to magnetic fields because all thermally self-compensated spring materials are magnetic. This may be noticeable when seismometers are operated in industrial areas or in the vicinity of dc-powered railway lines. Magnetic interferences by trains must especially be suspected when the long-period noise follows a regular timetable. Magnetic storms have frequently been seen in seismograms. At a very quiet site, the natural background variations of the geomagnetic field may limit the long-period resolution of a vertical sensor when its magnetic sensitivity exceeds  $0.5 \text{ m/s}^2$  per Tesla (Forbriger 2007, Forbriger et al. 2010). It is apparently difficult for manufacturers to avoid this level of magnetic sensitivity. Seismometers can also accidentally acquire a remanent magnetization during transportation or installation. Magnetic shielding (see 5.5.4 and IS 5.4) is therefore recommended at quiet sites.

### 5.3.7 The homogeneous triaxial arrangement

In order to observe ground motion in all directions, a triple set of seismometers oriented towards North, East, and upward (Z) has been the standard for a century. However, horizontal and vertical seismometers differ in their construction, and it takes some effort to make their responses equal. An alternative way of manufacturing a three-component set is to use three sensors of identical construction whose sensitive axes are inclined against the vertical like the edges of a cube standing on its corner (Fig. 5.10), by an angle of  $\arctan \sqrt{2}$ , or 54.7 degrees. A technical advantage of this concept is that the spring has to support only a fraction of the pendulum's weight, so the spring can be lighter and have a higher parasitic resonance.

The homogeneous-triaxial geometry was, with different intentions, introduced by Gal'perin (1955, 1977), Knothe (1963), and Melton and Kirkpatrick (1970), and is presently used in the Streckeisen STS2 and Nanometrics Trillium broadband seismometers.

**Fig. 5.10** The homogeneous triaxial geometry of the STS2 seismometer

Since most seismologists want finally to see the conventional E, N and Z components of motion, the oblique components U, V, W of the STS2 are electrically recombined according to

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \frac{1}{\sqrt{6}} \begin{pmatrix} -2 & 1 & 1 \\ 0 & \sqrt{3} & -\sqrt{3} \\ \sqrt{2} & \sqrt{2} & \sqrt{2} \end{pmatrix} \begin{pmatrix} U \\ V \\ W \end{pmatrix}. \quad (5.27)$$

The X axis of the STS2 seismometer is normally oriented towards East; the Y axis then points North. Noise originating in one of the sensors of a triaxial seismometer will appear on all three outputs (except for Y being independent of U). Its origin can be traced by transforming the X, Y and Z signals back to U, V and W with the inverse (transposed) matrix (programs **triax** and **rectax** (**lincomb** folder, section 5.8). Disturbances affecting only the horizontal outputs are unlikely to originate in the seismometer and are, in general, due to tilt. Disturbances of the vertical output only may be related to temperature, barometric pressure, or electrical problems common to all three sensors such as an unstable supply voltage.

### 5.3.8 Electromagnetic velocity sensing and damping

The simplest transducer both for sensing motions and for exerting forces is an electromagnetic (electrodynamic) device where a coil moves in the field of a permanent magnet, as in a loudspeaker (Fig. 5.11). The motion induces a voltage in the coil; a current flowing in the coil produces a force. From the conservation of energy it follows that the responsivity of the coil-magnet system as a force transducer, in Newtons per Ampere, and its responsivity as a velocity transducer, in Volts per meter per second, are identical. The units are in fact the same (remember that  $1\text{Nm} = 1\text{Joule} = 1\text{VAs}$ ). When such a velocity transducer is loaded with a resistor, permitting a current to flow, then according to Lenz's law it generates a force, opposing the motion. This effect is used to damp the mechanical free oscillation of passive seismic sensors (geophones and electromagnetic seismometers).

**Fig. 5.11** Electromagnetic velocity and force transducer.

We have so far treated the damping of passive sensors as if it were a viscous effect in the mechanical receiver. Actually, only a small part  $h_m$  of the damping is due to mechanical causes. The main contribution normally comes from the electromagnetic transducer, which is suitably shunted for this purpose. Its contribution is

$$h_{el} = E^2 / 2M\omega_0 R_d \quad (5.28)$$

where  $R_d$  is the total damping resistance (the sum of the resistances of the coil and of the external shunt). The total damping  $h_m + h_{el}$  is preferably chosen as  $1/\sqrt{2}$ , a value that defines a second-order Butterworth filter characteristic, and gives a maximally flat response in the passband (such as the velocity-response of the electromagnetic seismometer in Fig. 5.3).

### 5.3.9 Electronic displacement sensing

At very low frequencies, the output signal of electromagnetic transducers becomes too small to be useful for seismic sensing. One then uses active electronic transducers where a carrier signal, usually in the audio frequency range, is modulated by the motion of the seismic mass. The basic modulating device is an inductive or capacitive half-bridge. Inductive half-bridges are detuned by a movable magnetic core. They require no electric connections to the moving part and are environmentally robust; however their sensitivity appears to be limited by the granular nature of magnetism to something like  $10^{-10}$  m. Capacitive half-bridges (Fig. 5.12) are realized as three-plate capacitors where either the central plate or the outer plates move with the seismic mass. Their resolution is limited by the ratio between the electrical noise of the demodulator and the electrical field strength, and is, for modern broadband seismometers, typically better than  $10^{-12}$  m in the short-period teleseismic band. The comprehensive paper by Jones and Richards (1973) on the design of capacitive transducers still represents state-of-the-art in all essential aspects.

**Fig. 5.12** Capacitive displacement transducer (Blumlein bridge).

### 5.3.10 Electrochemical (MET) transducers

The motion of a liquid electrolyte in a tube can be sensed with fine mesh electrodes through which the liquid flows, by utilizing electrochemical effects at the interface between the electrodes and the liquid. According to one source ([www.mettechnology.com](http://www.mettechnology.com)) such sensors were first developed for the inertial guidance of German rocket weapons in the second world war, then investigated in the US but soon abandoned there, finally developed to practical usefulness in Russia based on theoretical work by V. A. Kozlov and V. Agafonof. The transducers were named Solions (from solution and ion) in the US and Molecular-Electronic (MET) by Russian authors.

In a partly filled circular tube or in a linear tube closed by elastic membranes, the liquid acts as a seismic mass, resulting in mechanically simple and very robust seismic sensors. Their transfer function is however not so simple because hydrodynamic and diffusive processes are involved. A description by poles and zeros as for pendulum-type sensors is mathematically inadequate although it can serve as an approximation. MET seismometers have some practical advantages: they are small and rugged, have a low power consumption, and don't need mass locking, mass centering or leveling. This makes them especially useful for ocean-bottom seismographs (see Chapter 7, section 7.5). They cannot, however, compete with observatory-grade pendulum instruments in other respects: resolution, precision, linearity. Force feedback is difficult to combine with the MET principle.

The MET principle is also used in rotational sensors where a circular tube is completely filled with the electrolyte. In this application they appear to be superior to mechanical devices; their symmetric design makes them virtually insensitive to linear acceleration. Rotational components of ground motion have been observed with MET sensors in the near-field of seismic sources, and with costly laser-gyroscopic devices at teleseismic distances from large earthquakes (see IS 5.3).

## 5.4 Force-balance accelerometers and seismometers

### 5.4.1 The force-balance principle

In a conventional passive seismometer, the inertia of the mass makes it move against the frame when the frame is accelerated, and the relative displacement or velocity of the mass is then converted into an electric signal. This principle of measurement is now used for short-period seismometers only. Broadband seismometers are built according to the force-balance principle. The inertial force is compensated (or 'balanced') with an electrically generated force

so that the seismic mass follows the motion of the frame; of course some small relative motion must remain because otherwise the inertial force could not be observed. The feedback force is generated with an electromagnetic force transducer or ‘forcer’ (Fig. 5.11). The electronic circuit (Fig. 5.13) is a servo loop, like in an analog chart recorder, and adjusts the feedback force so that the mass follows the motion of the frame.

**Fig. 5.13** Feedback circuit of a force-balance accelerometer (FBA).

The servo loop is most effective when it contains an integrator, in which case the offset of the mass is exactly nulled in the time average. (In a chart recorder, the difference between the input signal and a voltage indicating the pen position, is nulled). Due to unavoidable delays in the feedback loop, force-balance systems have a limited bandwidth; however, at frequencies where they are effective, they generate a feedback force that is proportional to ground acceleration. When the force is proportional to the current in the transducer, then the current, the voltage across the feedback resistor  $R$ , and the output voltage are all proportional to ground acceleration. Thus we have converted the acceleration into an electric signal without depending on the precision of a mechanical suspension.

The response of a force-balance system is approximately inverse to the gain of the feedback path. It can be easily modified by giving the feedback path a frequency-dependent gain. For example, if we make the capacitor  $C$  large so that it determines the feedback current, then the gain of the feedback path increases linearly with frequency and we have a system whose responsivity to acceleration is inverse to frequency and thus flat to velocity over a certain passband. We will look more closely at this option in section 5.4.3.

## 5.4.2 Force-balance accelerometers

Fig. 5.13 without the capacitor  $C$  represents the circuit of a force-balance accelerometer (FBA), a device that is widely used for earthquake strong-motion recording, for measuring tilt, and for inertial navigation. By equating the inertial and the electromagnetic force, it is easily seen that the responsivity (the output voltage per ground acceleration) is

$$U_{out} / \ddot{x} = MR / E \quad (5.29)$$

where  $M$  is the seismic mass,  $R$  the total resistance of the feedback path, and  $E$  the responsivity of the forcer (in  $N/A$ ). The conversion is determined by only three passive components of which the mass is error-free by definition (it defines the inertial reference), the resistor is a nearly ideal component, and the force transducer very precise because the motion is small. Some accelerometers do not have a built-in feedback resistor; the user can insert a

resistor of his own choice and thus select the gain. The responsivity in terms of current per acceleration is simply  $I_{out} / \ddot{x} = M / E$ .

FBA's work down to zero frequency but the servo loop becomes ineffective at some upper corner frequency  $f_0$  (usually a few hundred to a few thousand Hz), above which the arrangement acts like an ordinary inertial displacement sensor. The feedback loop behaves like an additional stiff spring; the response of the FBA sensor corresponds to that of a mechanical pendulum with the eigenfrequency  $f_0$ , as schematically represented in the left panels of Fig. 5.3.

### 5.4.3 Velocity broadband seismometers

For broadband seismic recording with high sensitivity, an output signal proportional to ground acceleration is unfavorable. At high frequencies, sensitive accelerometers are easily saturated by traffic noise or impulsive disturbances. At low frequencies, a system with a response flat to acceleration generates a permanent voltage at the output as soon as the suspension is not completely balanced. The system might then be saturated by the offset voltage resulting from thermal drift or tilt. What we need is a band-pass response in terms of acceleration, or equivalently a high-pass response in terms of ground velocity, like that of a normal electromagnetic seismometer (geophone, right panels in Fig. 5.3) but with a lower corner frequency.

The desired velocity broadband (VBB) response is obtained from the FBA circuit by adding paths for differential feedback and integral feedback (Fig. 5.14). A large capacitor  $C$  is chosen so that the differential feedback dominates throughout the desired passband. While the feedback current is still proportional to ground acceleration as before, the voltage across the capacitor  $C$  is a time integral of the current, and thus proportional to ground velocity. This voltage serves as the output signal. The output voltage per ground velocity, i.e. the apparent generator constant  $E_{app}$  of the feedback seismometer, is

$$E_{app} = V_{out} / \dot{x} = M / EC . \quad (5.30)$$

Again the response is essentially determined by three passive components. Although a capacitor with a solid dielectric is not quite as ideal a component as a good resistor, the response is still linear and very stable.

**Fig. 5.14** Feedback circuit of a VBB (velocity-broadband) seismometer. As in Figure 5.13, the seismic mass is the summing point of the inertial force and the negative feedback force.

The output signal of the second integrator is normally accessible at the „mass position“ output. It does not indicate the actual position of the mass but indicates where the mass would go if the feedback were switched off. „Centering“ the mass of a feedback seismometer has the effect of discharging the integrator so that its full operating range is available for the seismic signal. The mass-position output is not normally used for seismic recording but is useful as a state-of-health diagnostic, and is used in some calibration procedures.

The relative strength of the integral feedback increases at lower frequencies while that of the differential feedback decreases. These two components of the feedback force are of opposite phase ( $-\pi/2$  and  $\pi/2$  relative to the output signal, respectively). At certain low frequency, the two contributions are of equal strength and cancel each other out. This is the lower corner frequency of the closed-loop system. Since the closed-loop response is inverse to that of the feedback path, one would expect to see a resonance in the closed-loop response at this frequency. However, the proportional feedback remains and damps the resonance; the resistor  $R$  acts as a damping resistor. At lower frequencies, the integral feedback dominates over the differential feedback, and the closed-loop response to ground velocity decreases with the square of the frequency. As a result, the feedback system behaves like a conventional electromagnetic seismometer and can be described by the usual three parameters: free period, damping, and generator constant. In fact, electronic broadband seismometers, even if their actual electronic circuit is more complicated than presented here, follow the simple theoretical response of electromagnetic seismometers more closely than those ever did.

As far as the response is concerned, a force-balance circuit as described here may be seen as a means to convert a moderately stable short- to medium-period suspension into a stable electronic long-period or very-long-period seismometer. The corner period may be increased by a large factor, for example 24-fold (from 5 to 120 sec) in the STS2 seismometer or even 200-fold (from 0.6 to 120 sec) in CMG3 and Trillium seismometers. But this factor says little about the performance of the system. Feedback does not reduce the instrumental noise; a large extension of the bandwidth is useless when the system is noisy. According to Eq. (5.26), short-period suspensions must be combined with extremely sensitive transducers for a satisfactory sensitivity at long periods.

At some high frequency, the loop gain falls below unity. This is the upper corner frequency of the feedback system which marks the transition from a response flat to velocity to one flat to displacement. A well-defined and nearly ideal behavior of the seismometer, like at the lower corner frequency, should not be expected here both because the feedback becomes ineffective and because most suspensions have parasitic resonances slightly above the electrical corner frequency (otherwise they could have been designed for a larger bandwidth). The detailed response at the high-frequency corner, however, rarely matters since the upper corner frequency is usually outside the passband of the record. Its effect on the transfer function in most cases can be modeled as a small, constant delay (a few milliseconds) over the whole VBB passband.

#### **5.4.4 Other methods of bandwidth extension**

The force-balance principle permits the construction of high-performance, broadband seismic sensors but is not easily applicable to geophone-type sensors because fitting a displacement transducer to these is difficult. Sometimes it is desirable to broaden the response of an existing geophone without a mechanical redesign.

The simplest solution is to send the output signal of the geophone through a filter that removes its original response (this is called an inverse filtration) and replaces it by some other desired response, preferably that of a geophone with a lower eigenfrequency. The analog, electronic version of this process would only be used in connection with direct visible recording; for all other purposes, one would implement the filtration digitally as part of the data processing.

Alternatively, the bandwidth of a geophone may be enlarged by strong damping. This does not enhance the gain outside the passband but rather reduces it at and around the eigenfrequency; nevertheless, after appropriate amplification, the net effect is an extension of the bandwidth towards longer periods. Strong damping is obtained by connecting the coil to a preamplifier whose input impedance is negative. The total damping resistance, which is otherwise limited by the resistance of the coil (Eq. (5.28)), can then be made arbitrarily small. The response of the over-damped geophone is flat to acceleration around its free period. It can be made flat to velocity by an approximate (band-limited) integration. This technique is used in the Lennartz Le-1d and Le-3d seismometers (see DS 5.1) whose electronic corner period can be up to 40 times larger than the mechanical one. Although these are not strictly force-balance sensors, they take advantage of the fact that active damping (which is a form of negative feedback) greatly reduces the relative motion of the mass.

## 5.5 Seismic noise, site selection and installation

Electronic seismographs can be designed for any desired magnification of the ground motion. A practical limit, however, is imposed by the presence of undesired signals which must not be magnified so strongly as to obscure the record. Such signals are usually referred to as noise and may be of seismic, instrumental, or environmental origin. Seismic noise is treated in Chapter 4; see also exercise EX\_4.1. Instrumental self-noise may have mechanical and electronic sources and will be discussed in the next section. Here we focus on those general aspects of site selection and of seismometer installation aimed at the reduction of environmental noise. For technical details on site selection as well as vault, tunnel and borehole installations see Chapter 7. More recommendations for proper deployment and shielding of seismometers are summarized in the information sheet IS 5.4.

### 5.5.1 The USGS low-noise model

**Fig. 5.15** The USGS New Low Noise Model (NLNM), here expressed as RMS amplitude of ground acceleration in a constant relative bandwidth of one-sixth decade.

The USGS low-noise model (Peterson, 1993; see Fig. 5.15) is a graphical and numerical representation of the lowest vertical seismic noise levels observed worldwide, and is extremely useful as a reference for the quality of a site or of an instrument. A recent compilation of minimum noise levels by Berger et al. (2004) has essentially confirmed the validity of the NLNM below 5 Hz; at higher frequencies the NLNM appears to be somewhat too low. Origin and properties of seismic noise are discussed in Chapter 4. The **noisecon** program (section 5.8) can be used to convert power spectral densities of the NLNM into other units (such as rms amplitudes in a given bandwidth) and vice versa.

## 5.5.2 Site selection

Site selection for a permanent station is always a compromise between two conflicting requirements: infrastructure and low seismic noise. The noise level depends on the geological situation and on the proximity of sources, some of which are usually associated with the infrastructure. A seismograph installed on solid basement rock can be expected to be fairly insensitive to local disturbances while one sitting on a thick layer of soft sediments will be noisy even in the absence of identifiable sources. As a rule, the distance from potential sources of noise, such as roads and inhabited houses, should be very much larger than the thickness of the sediment layer. Broadband seismographs can be successfully operated in major cities when the geology is favorable; in unfavorable situations, such as in sedimentary basins, only deep mines and boreholes may offer acceptable noise levels (see 4.3.2, 7.4.3 and 7.4.5).

By definition of the Low Noise Model, most sites have a noise level above the NLNM, sometimes by a large factor. This factor, however, is not uniform over time or over the seismic frequency band. At short periods ( $< 2$  s), a noise level within a factor of 10 of the NLNM may be considered very good in most areas. Short-period noise at most sites is predominantly man-made, lower during nighttime, and somewhat larger in the horizontal components than in the vertical. At intermediate periods (2 to 20 s), marine microseisms dominate. They have similar amplitudes in the horizontal and vertical components and have large seasonal variations. In winter they may be 50 dB above the NLNM. At longer periods, the vertical ground noise is often within 10 or 20 dB of the NLNM even at otherwise noisy stations. Horizontal long-period noise may nevertheless be horrible at the same station due to tilt-gravity coupling (5.3.3). It may be larger than vertical noise by a factor of up to 300, the factor increasing with period. Therefore, a site can be considered as favourable when the horizontal noise at 100 to 300 s is within 20 dB (i.e., a factor of 10 in amplitude) above the vertical noise. Tilt may be caused by traffic, wind, or local fluctuations of the barometric pressure. Large tilt noise is sometimes observed on concrete floors when an unventilated cavity exists underneath; the floor then acts like a membrane. Such noise can be identified by its linear polarization and its correlation with the barometric pressure. Even on an apparently solid foundation, the long-period noise often correlates with the barometric pressure (see Beauduin et al., 1996). If the situation can not be remedied otherwise, the barometric pressure should be recorded with the seismic signal and used for a correction. An example of barometric noise is shown in Fig. 2.21 of Chapter 2. For very-broadband seismographic stations, barometric recording is generally recommended.

Besides ground noise, environmental conditions must be considered. An aggressive atmosphere may cause corrosion, wind and short-term variations of temperature may induce

noise, and seasonal variations of temperature may exceed the manufacturer's specifications for unattended operation. Seismometers must be protected against these conditions, sometimes by hermetic containers as described in the next subsection. Suggestions for vault design have been given by Uhrhammer and Karavas (1997) and Trnkoczy (1998) and more recently by the PASSCAL Instrument Center (2009a). Since it is difficult to prevent water from accumulating in vaults, installation of a drainage or a sump pump should be considered (Passcal Instrument Center 2009b).

### 5.5.3 Seismometer installation

We briefly describe the installation of a portable broadband seismometer inside a building, vault, or cave. First, the orientation of the sensor is marked on the floor. This is best done with a geodetic gyroscope, but a magnetic compass will do in most cases. The magnetic declination must be taken into account. Since a compass may be deflected inside a building, the direction should be taken outside and transferred to the site of installation. Spirit levels combined with a laser, and especially laser cross levels, are most convenient tools for orienting seismometers, and are available at low cost from do-it-yourself stores. When the magnetic declination is unknown or unpredictable (such as at high latitudes or in volcanic areas), the orientation should be determined with a sun compass.

To isolate the seismometer from stray currents, small glass or Plexiglas plates should be cemented to the ground under its feet. Then the seismometer is installed, tested, and wrapped with a layer of soft, thermally insulating material such as fiber wool or a synthetic fleece blanket. It is essential that the inner heat shield is so soft that it cannot transport substantial forces to the sensor. An additional heat-reflecting blanket (commonly sold as "space blanket" or "rescue blanket") protects the sensor from thermal radiation and air drafts. The thermal shield should also cover the floor around the seismometer (see Figures 1 to 5 in IS 5.4). The use of Styrofoam seeds is not recommended; they have been observed to cause mechanical noise. Stiff shields such as Styrofoam boxes provide additional protection but must not touch the sensor. The self-heating of electronic seismometers can induce convection in any open space inside the insulation; it is therefore important that the insulation leaves no gap around the seismometer, or at most a gap that is only a few millimeters wide.

For a permanent installation under unfavourable environmental conditions, the seismometer should be enclosed in a hermetic container. A problem with such containers (as with all seismometer housings) is, however, that they cause tilt noise when they are deformed by the barometric pressure. Essentially three precautions are possible: (1) either the base-plate is carefully cemented to the floor, or (2) it is made so massive that its deformation is negligible, or (3) a "warp-free" design is used, as described by Holcomb and Hutt (1992) for the STS1 seismometers. Some fresh desiccant (Silica gel) should be placed inside the container, even into the vacuum bell of STS1 seismometers. Cable connectors corrode easily in a humid environment. All extra connectors and auxiliary electronic equipment should therefore be protected with closed (as far as possible) plastic bags and desiccant. Fig. 5.16 illustrates the shielding of the STS2 seismometers (see DS 5.1) in the German Regional Seismic Network (GRSN). For more details see Figures 1 to 7 in IS 5.4. Guidelines for the installation of broadband seismometers can also be found in Uhrhammer et al. (1998) and more specifically for the installation of both weak-motion (short-period and broadband) and strong-motion seismometers on land, in vaults, tunnels, mines and boreholes as well as in the ocean environment in the Sub-chapters 7.4 and 7.5 of this Manual.

**Fig. 5.16** The STS2 seismometer of the GRSN inside its shields.

#### 5.5.4 Magnetic shielding

Magnetic shields can be manufactured from Permalloy (Mu-metal) but they are expensive and of limited efficiency. An active compensation may be preferable. Such a device might consist of a three-component fluxgate magnetometer that senses the field near the seismometer, an electronic driver circuit in which the signal is integrated with a short time constant (a few milliseconds) and amplified, and a three-component set of Helmholtz coils that compensate changes of the magnetic field (see Figures 6 and 7 in IS 5.4). The permanent geomagnetic field should not be compensated; the resulting offsets of the fluxgate outputs can be compensated electrically before the integration, or with a small permanent magnet mounted near the fluxgate.

#### 5.5.5 Instrumental self-noise

All modern seismographs use semiconductor amplifiers which, like other active (power-dissipating) electronic components, produce continuous electronic noise whose origin is manifold but ultimately related to the quantization of the electric charge. Electromagnetic transducers, such as those used in geophones, also produce thermal electronic noise (resistor noise, Johnson noise). The contributions from semiconductor noise and resistor noise are often comparable, and together limit the sensitivity of the system. Another source of continuous noise, the Brownian (thermal) motion of the seismic mass, may be noticeable when the mass is very small (less than a few grams). Presently manufactured observatory-grade seismometers have sufficient mass to make the Brownian noise negligible against noise from other sources and we will therefore not discuss it here. Seismographs may also suffer from transient disturbances originating in slightly defective semiconductors or in stressed mechanical parts of the seismometer. The present section is mainly concerned with identifying and measuring instrumental noise.

### 5.5.6 Self-noise of electromagnetic short-period seismographs

Electromagnetic seismometers and geophones are passive sensors whose self-noise is of purely thermal origin and does not increase at low frequencies as it does in active (power-dissipating) devices. Their output signal level, however, is comparatively low, so a low-noise preamplifier (Fig. 5.17) must be inserted between the geophone and the recorder. We will call this combination an electromagnetic seismograph or EMS. Unfortunately the preamplifier noise does increase at low frequencies and limits the overall sensitivity. EMSs are now rarely used for long-period or broadband recording because of the superior performance of feedback instruments.

The sensitivity of an EMS is normally limited by amplifier noise. However, this noise does not depend on the amplifier alone but also on the impedance of the electromagnetic transducer coil (which can be chosen within wide limits). Up to a certain impedance the amplifier noise voltage is nearly constant, but then it increases linearly with the impedance, due to a noise current flowing out of the amplifier input. On the other hand, the signal voltage increases with the square root of the coil impedance. The best signal-to-noise ratio is therefore obtained with an optimum source impedance defined by the corner between voltage and current noise in the graph of total noise vs. source impedance, and is different for each type of amplifier and also depends on frequency. Vice versa, when the transducer is given, the amplifier must be selected for low noise at the relevant impedance and frequency.

**Fig. 5.17** Two alternative circuits for an EMS preamplifier with a low-noise op-amp. The non-inverting circuit is generally preferable when the damping resistor  $R_I$  is much larger than the coil resistance and the inverting circuit when it is comparable or smaller. However, the relative performance also depends on the noise specifications of the op-amp. The gain is adjusted with  $R_g$ .

The electronic noise of an EMS can be predicted when the technical data of the sensor and the amplifier are known. Semiconductor noise increases at low frequencies; amplifier specifications must apply to seismic rather than audio frequencies. In combination with a given sensor, the noise can then be expressed as an equivalent seismic noise level and compared to real seismic signals or to the NLNM (Fig. 5.15). As an example, Fig. 5.18 shows the self-noise of one of the better seismometer-amplifier combinations. It resolves minimum ground noise between 0.1 and 10 s period. Discussions and more examples are found in Riedesel et al. (1990) and in Rodgers (1992, 1993 and 1994). The result is easily summarized:

Most well-designed seismometer-amplifier combinations resolve minimum ground noise up to 6 or 8 s period, that is, to the microseismic peak. A few of them may make it to about 15 s; they marginally resolve the secondary microseismic peak. To resolve minimum ground noise up to 30 s is hopeless, as is obvious from Fig. 5.18. Ground noise falls and electronic noise

risers so rapidly beyond a period of 20 s that the crossover point can not be substantially moved towards longer periods. Of course, at a reduced level of sensitivity, restoring long-period signals from short-period sensors may make sense, and the long-period surface waves of sufficiently large earthquakes may well be recorded with short-period electromagnetic seismometers.

**Fig. 5.18** Electronic self-noise of the input stage of a short-period seismograph. The EMS is a Sensonics Mk3 with two 8 kOhm coils in series and tuned to a free period of 1.5 s. The amplifier is the LT1012 op-amp. The curves a and b refer to the circuits of Fig. 5.17. NLNM is the USGS New Low Noise Model (Fig. 5.15). The ordinate gives rms noise amplitudes in dB relative to  $1 \text{ m/s}^2$  in 1/6 decade.

Amplifier noise can be observed by locking the sensor or tilting it so that the mass is firmly at a stop, or by replacing it with a resistor that has the same resistance as the coil. If these manipulations do not significantly reduce the noise, then obviously the EMS does not resolve seismic noise. However, this is only a test, not a way to precisely measure the electronic self-noise. A locked sensor or a resistor do not exactly represent the electric impedance of the unlocked sensor.

### 5.5.7 Self-noise of force-balance seismometers

Although the self-noise of force-balance seismometers can theoretically be predicted from that of its components, such a prediction may be unrealistic because certain sources of noise appear only under operating conditions. Anyhow, the user can hardly test the components without destroying the instrument. The electronic circuit cannot be tested when the mass is locked. The instrumental noise can thus only be observed under operating conditions, in the presence of seismic signals and seismic noise.

Although seismic noise is generally a nuisance in this context, natural signals may also be useful as test signals. Marine microseisms should be visible on any sensitive seismograph whose seismometer has a free period of one second or longer; they normally are the strongest continuous signal in a broadband trace. However, their amplitude exhibits large seasonal and geographical variations. For broadband seismographs at quiet sites, the tides of the solid Earth are a reliable and predictable test signal. They have a predominant period of slightly less than 12 hours and an amplitude in the order of  $10^{-6} \text{ m/s}^2$ . While normally invisible in the raw data, they may be extracted by low-pass filtration with a corner frequency of 1 mHz. For this

purpose it is helpful to have the data available with a sampling rate of 1 per second or less. By comparison with the predicted tides, the gain and polarity of the seismograph may be checked (e.g. Davis and Berger 2007). A seismic broadband station that records Earth's tides is likely to be up to international standards.

### 5.5.8 Coherency analysis

For a quantitative determination of instrumental noise, two or three instruments must be operated side by side (Holcomb, 1989, 1990; Sleeman et al. 2006). One can then determine the coherency between the records and assume that coherent noise is seismic and incoherent noise is instrumental. This works well if one has a quiet site and a good reference instrument, but the method is not safe. The seismometers may respond coherently to environmental disturbances caused by barometric pressure, temperature, the supply voltage, magnetic fields, vibrations, or electromagnetic waves. Nonlinear behavior (intermodulation) may produce coherent but spurious long-period signals. When no good reference instrument is available, then different instrument types should be used in the test that are unlikely to respond in the same way to environmental disturbances.

The coherency analysis is somewhat tricky in detail when only two instruments are available. When the transfer functions of both instruments are precisely known, it is in fact theoretically possible to determine the seismic signal and the instrumental noise of each instrument separately as a function of frequency. Alternatively, one may assume that the transfer functions are not so well known but the reference instrument is noise-free; in this case the noise and the relative transfer function of the other instrument can be determined. The coherency test with three instruments after Sleeman et al. (2006) permits to determine the relative transfer functions and the instrumental noise of each instrument at the same time, so it requires no questionable assumptions. It may fail, however, when physically different sources of noise are present such as seismic and magnetic noise to which the instruments do not have a uniform response (they may, for example, have the same response to seismic but not to magnetic noise). As with all statistical methods, very long time series or multiple observations are required for significant results. We offer the computer programs **twocrosp** and **tricrosp** for the analysis (see 5.8, **sleeman** folder).

### 5.5.9 Transient disturbances

Most new seismometers produce spontaneous transient disturbances, quasi miniature earthquakes caused by stresses in the mechanical components. Although they do not necessarily originate in the spring, their waveform at the output seems to indicate a sudden and permanent (step-like) change in the spring force. Long-period seismic records are sometimes severely degraded by such disturbances. The transients often die out within months or years; if they do not, and especially when their frequency increases, corrosion must be suspected. Manufacturers try to mitigate the problem with a low-stress design and by aging the components or the finished seismometer (by extended storage, vibrations, or heating and cooling cycles). It is sometimes possible to release stresses and eliminate transient disturbances by hitting the pier around the seismometer with a hammer, a procedure that is recommended in each new installation.

## 5.6 Seismometer calibration

### 5.6.1 Electrical and mechanical calibration

The calibration of a seismometer establishes knowledge of the relationship between its input (the ground motion) and its output (an electric signal), and is a prerequisite for a reconstruction of the ground motion. Since precisely known ground motions are difficult to generate, one makes use of the equivalence between ground acceleration and an external force on the seismic mass, and calibrates seismometers with an electromagnetic force generated in a calibration coil. This is called an electrical or relative calibration. In the case of feedback seismometers an electrical calibration essentially characterizes the electronic feedback circuit but not the mechanical receiver. Only if the factor of proportionality between the current in the coil and the equivalent ground acceleration is known, the absolute responsivity to ground motion can be determined from an electric calibration. Otherwise, it must be determined from a mechanical experiment in which the seismometer is subject to a known mechanical motion or a tilt. This is called a mechanical or absolute calibration. Since precise mechanical calibration signals are difficult to generate over a large bandwidth, one does not normally attempt to determine the complete transfer function in this way.

Sub-sections 5.6.2 to 5.6.7 are is mainly concerned with the electrical (relative) calibration although some methods may also be used for the mechanical calibration on a shake table (5.6.9). Procedures for the absolute mechanical calibration that do not require a shake table are presented in in 5.6.10 and 5.6.11.

### 5.6.2 General conditions

Calibration experiments are disturbed by seismic noise and tilt and should therefore be carried out in a basement room. However, the large operating range of modern seismometers permits a calibration with relatively large signal amplitudes, making background noise less of a problem than one might expect. Thermal drift is more serious because it interferes with the long-period response of broadband seismometers. For a calibration at long periods, seismometers must be protected from draft and allowed sufficient time to reach thermal equilibrium. Visible and digital recording in parallel is recommended. Recorders must be absolutely calibrated before they can serve to absolutely calibrate seismometers. **The input impedance of recorders and the source impedance of sensors must be measured so that a correction can be applied for the voltage drop in the source impedance.**

### 5.6.3 Specific procedures for geophones

Geophones usually have no calibration coil. The calibration current must then be sent through the signal coil where it produces an ohmic voltage in addition to the output signal generated by the motion of the mass. The undesired voltage can be compensated in a bridge circuit (Willmore 1959); the bridge is zeroed with the seismic mass locked or at a stop. When the calibration current and the output voltage are digitally recorded, it is more convenient to use only a half-bridge (Fig. 5.19) and to compensate the ohmic voltage numerically. The program **calex** (section 5.8) can do this automatically. The residual (the difference between the actual and the modeled response) is often dominated by nonlinear distortions (5.7).

**Fig. 5.19** Half-bridge circuit for calibrating electromagnetic seismometers

Geophones can be absolutely calibrated without a mechanical input provided that the total moving mass  $M$  is known and its motion is linear. In an electric calibration a geophone behaves like a resonant electric circuit. Its electrical impedance is

$$\tilde{Z}(\omega) = R_C + \frac{E^2}{\omega_0 M} \cdot \frac{j\omega\omega_0}{-\omega^2 + 2j\omega\omega_0 h + \omega_0^2} \quad (5.31)$$

$R_C$  is the ohmic resistance of the coil,  $E$  is the generator constant of the electromagnetic transducer as in 5.2.8. The term after the plus sign is the response of a resonant electric circuit consisting of a capacitor  $C=M/E^2$ , an inductor  $L=E^2/S$ , and a resistor  $R_D=E^2/D$  in parallel.  $M$ ,  $S$ , and  $D$  are the mechanical components of the pendulum as in 5.2.7. The analysis of the resonant response, either in time or in frequency domain, supplies all desired parameters when  $M$  is known. For an analysis in time domain, it is convenient to excite a transient response by interrupting a current through the signal coil (Willmore 1979, Rodgers et al. 1995). In this case the ohmic voltage disappears when the transient response begins. **calex** can also be used here.

Another approach is illustrated in fig. 5.20. The electromagnetic part of the numerical damping is inversely proportional to the total damping resistance, the factor of proportionality being  $E^2 / 2M\omega_0$ . The generator constant  $E$  can thus be calculated from relative calibrations with different resistive loads, independent of the method used for the relative calibration.

**Fig. 5.20** Determining the generator constant from a plot of damping versus total damping resistance  $R_d = R_{coil} + R_{load}$ . The horizontal units are microsiemens (reciprocal Megohms).

### 5.6.4 Calibration with sinewaves (obsolete)

With a sinusoidal input, the output of a linear system is also sinusoidal, and the ratio of the two signal amplitudes is the absolute value of the transfer function. An experiment with sinewaves therefore permits a direct check of the transfer function, without any a-priori knowledge of its mathematical form and without waveform modeling. This is often the first step in the identification of an unknown system. A computer program would however be required to derive a parametric representation of the response from the measured values. A calibration with arbitrary signals, as described later, is more straightforward for this purpose.

Calibration with sinewaves is time-consuming because the system must reach a steady state after each change of frequency, which can take more than 10 minutes for some broadband seismometers. The gain and phase delay can be read manually from a plotted Lissajous ellipse as in Fig.5.21. The accuracy of the evaluation depends on the purity of the sinewave. A better accuracy is obtained by numerical analysis of digitally recorded data. By fitting sinewaves to the signals, amplitudes and phases can be extracted for just one precisely known frequency at a time; distortions of the input signal don't matter then. If the test frequency is not digitally controlled, then it should be fitted as well. The fit should be computed for an integer number of cycles, and offsets should be removed from the data. We offer a computer program **sinfit** for this purpose (section 5.8, **sinical** folder). Although the method is now obsolete for the purpose of calibration, it is useful for investigating unmodelled details of the response such as parasitic resonances; these might be lost in a more time-efficient broadband calibration. Another surviving application is the calibration of passive short-period seismometers in seismic stations where sinewaves can be remotely applied to the calibration coil but no other test signals are available. The evaluation can be done with a **sinical** program (section 5.8).

**Fig. 5.21** Measuring the phase between two sine-waves with a Lissajous ellipse.

Eigenfrequency  $f_0$  and damping  $h$  of seismometers with a conventional response can be determined graphically with a set of standard resonance curves on double-logarithmic paper. The measured amplitude ratios are plotted as a function of frequency  $f$  on the same type of paper and overlain with the standard curves (Fig. 5.22). The desired quantities can be read directly. The method is simple but not very accurate.

EX 5.3 by J. Bribach and Ch. Teupser can be used for seismometer calibration by harmonic drive.

Fig. 5.22 Normalized resonance curves.

### 5.6.5 Step response and weight-lift test (obsolete)

The simplest, but only moderately accurate and now historical, calibration method is to observe the response of the system to a step input. The step signal can be generated by switching on or off a current through the calibration coil, or by applying or removing a constant mechanical force on the seismic mass, usually by lifting a weight. Horizontal sensors used to be absolutely calibrated with a V-shaped thread attached to the mass at one end, to a fixed point at the other end, and to the test weight at half length. The thread was then burned off for a soft release.

The step-response experiment can be used both for a relative and an absolute calibration; when applicable, it is probably the simplest method for the latter. Using a known test weight  $w$  and knowing the seismic mass  $M$ , we also know the test signal: it is a step in acceleration whose magnitude is  $w/M$  times gravity (times a geometry factor when the force is applied through a thread). In case of a rotational pendulum, a correction factor must be applied when the force does not act at the center of gravity. The method has lost its former importance because the seismic mass of modern seismometers is not easily accessible, and the correction factor for rotational motion is not supplied by the manufacturers.

In the context of relative calibration, the step-response method is still useful as a quick and intuitive test, and has the advantage that it can be visually evaluated. The **calex** method covers the step response as well. Fig. 5.23 shows the characteristic step responses of second-order high-pass, band-pass, and low-pass filters with  $1/\sqrt{2}$  of critical damping.

**Fig. 5.23** Normalized step responses of second-order high-pass, band-pass and low-pass filters.

Each response is a strongly damped oscillation around its asymptotic value. With the specified damping, the systems are Butterworth filters, and the amplitude decays to  $e^{-\pi}$  or 4.3% within one half-wave. The ratio of two subsequent amplitudes of opposite polarity is known as the overshoot ratio. It can be evaluated for the numerical damping  $h$ : when  $x_i$  and  $x_{i+n}$  are two (peak-to-peak) amplitudes  $n$  periods apart, with integer or half-integer  $n$ , then

$$\frac{1}{h^2} = 1 + \left( \frac{2\pi n}{\ln x_i - \ln x_{i+n}} \right)^2. \quad (5.32)$$

The free period, in principle, can also be determined from the impulse or step response of the damped system but should be measured preferably without electrical damping so that more oscillations can be observed. A system with the free period  $T_0$  and damping  $h$  oscillates with the period  $T_0 / \sqrt{1 - h^2}$  and the overshoot ratio  $\exp(-\pi h / \sqrt{1 - h^2})$ .

### 5.6.6 Calibration with arbitrary signals

In most cases, the purpose of calibration is to obtain the parameters of an analytic representation of the transfer function. Assuming that its mathematical form is known, the task is to determine the parameters from an experiment in which both the input and the output signals are known. As compared to other methods where a predetermined input signal is used and only the output signal is recorded, recording both signals has the additional advantage of eliminating the transfer function of the recorder from the analysis.

Calibration is a classical inverse problem that can be solved with standard least-squares methods. The general solution is schematically depicted in Fig. 5.24. A computer algorithm (filter 1) is implemented that represents the seismometer as a filter and permits the computation of its response to an arbitrary input. An inversion scheme (3) is programmed around the filter algorithm in order to find best-fitting filter parameters for a given pair of input and output signals. The purpose of filter 2 is explained below. The sensor is then calibrated with a test signal (4) for which the response of the system is sensitive to the unknown parameters but which is otherwise arbitrary. When the system is linear, parameters obtained from one test signal will also predict the response to the other signal.

**Fig. 5.24** Block diagram of the **calex** procedure. Storage and retrieval of the data are omitted from the figure.

When the transfer function has been correctly parameterized and the inversion has converged, then the residual error consists mainly of noise, drift, and nonlinear distortions. At a signal level of about one-third of the operating range, typical residuals are 0.03% to 0.05% rms for force- balance seismometers and  $\geq 1\%$  for passive electrodynamic sensors.

The approximation of a rational transfer function with a discrete filtering algorithm is not trivial. The program **calex** (section 5.8) uses an impulse-invariant recursive filter (Schuessler, 1981). This method formally requires that the seismometer has a negligible response at frequencies outside the Nyquist bandwidth of the recorder, a condition that is severely violated by most digital seismographs; but this problem can be circumvented with an additional digital low-pass filtration (Filter 2 in Fig. 5.24) that limits the bandwidth of the simulated system. Signals from a typical calibration experiment are shown in Fig. 5.25. A sweep as a test signal permits the residual error to be visualized as a function of time or frequency. Since essentially only one frequency is present at a time, the time axis may as well be interpreted as a frequency axis.

With an appropriate choice of the test signal, other methods like the calibration with sine-waves step functions, random noise or random telegraph signals, can be duplicated and compared to each other. An advantage of the **calex** algorithm is that it makes no use of special properties of the test signal, such as being sinusoidal, periodic, step-like or random. Therefore, test signals can be short (a few times the free period of the seismometer) and can be generated with the most primitive means, even by hand (you may turn the dial of a sinewave generator by hand, or even produce the test signal with a battery and a switch or potentiometer). A breakout box or a special cable may, however, be required for feeding the calibration signal into the digital recorder.

For a quick and easy check of the transfer function, the simple method of spectral division may be sufficient. When the input signal (the stimulus) and the output signal (the response) have both been recorded, and if the system was quiet at the beginning and the end of the record, then dividing the Fourier transform of the output signal by that of the input signal may result in a reasonable approximation to the actual response, at least in a limited bandwidth. A parametric (mathematical) representation of the response, such as by poles and zeros, is however more difficult to obtain in this way.

**Fig. 5.25** Electrical calibration of an STS2 seismometer with **calex**. Traces from top to bottom: input signal (a sweep with a total duration of 10 min); output signal; synthetic output signal; residual. The rms residual is 0.05 % of the rms output. See also EX 5.4.

Some other routines for seismograph calibration and system identification are contained in the PREPROC software package (Plešinger et al., 1996).

### 5.6.7 Specific procedure for triaxial seismometers

In homogeneous-triaxial seismometers such as the Streckeisen STS2 and the Nanometrics Trillium models, transfer functions in a strict sense can only be attributed to the individual U, V, W sensors, not to the X, Y, Z outputs. Formally, the response of a triaxial seismometer to arbitrary ground motions is described by a nearly diagonal 3 x 3 matrix of transfer functions relating the X, Y, Z output signals to the X, Y, Z ground motions. This is also true for conventional three-component sets if they are not perfectly aligned; only the composition of the matrix is different.

However, if the U, V, W sensors are reasonably well matched, then we need not care about a matrix of transfer functions. The X, Y, Z channels can then each be described by a single transfer function that is a weighted average of those of the U, V, W sensors:

$$\begin{pmatrix} T_X \\ T_Y \\ T_Z \end{pmatrix} = \frac{1}{6} \begin{pmatrix} 4 & 1 & 1 \\ 0 & 3 & 3 \\ 2 & 2 & 2 \end{pmatrix} \begin{pmatrix} T_U \\ T_V \\ T_W \end{pmatrix} \quad (5.33)$$

This formula applies to transfer functions or parameters but not to signals; the matrix elements in (5.33) are the squares of those in 5.27. For any real instrument they will differ slightly from their nominal values but this is negligible in the present context.

The X, Y, Z outputs can thus be calibrated as if they represented single-component sensors. In order to simulate a ground acceleration in one of the X, Y, or Z directions, simultaneous currents must be sent through the U, V, W calibration coils so that an output signal appears only at one of the X, Y, Z outputs. For the Z component this requires equal currents through the U, V, W coils. For the X or Y direction, the three currents must however have different magnitudes and polarities, which requires a slightly more complicated test arrangement. This inconvenience is circumvented by a procedure introduced by Peter Davis (UCSD): calibrate the vertical output with equal currents into the U, V, W coils but record the X and Y output signals as well. Unless all transfer functions happen to be identical, small residual signals will appear at the X and Y outputs. They contain information on the X and Y transfer functions. Use the inverse (transposed) of the signal transformation matrix (5.27) to reconstruct the U, V, W signals, analyze these for their transfer functions, and recombine the results according to (5.33). A computer program **trical**, essentially a combination of **triax** and **calex**, is available for this procedure (section 5.8, **calex** folder). The experiment normally requires four digitizer channels; if only three are available, one must use a predetermined stimulus such as a pseudo-random telegraph signal that can be numerically duplicated.

Using ground noise or other seismic signals, an unknown sensor can be calibrated against a known one by operating the two sensors side by side (Pavlis and Vernon, 1994). The method is limited to a frequency band where suitable seismic signals occur well above the instrumental noise level and are spatially coherent between the two instruments. The instruments must be close to each other on the same pier. The frequency response and the gain of the unknown instrument can be determined at the same time. We offer a program **inverseif** (section 5.8) for this analysis. If the frequency response of both sensors is already known or can be measured electrically, then it will suffice to deconvolve both records to a common response and compare the signal amplitudes in a frequency band where the waveforms are identical.

In a similar way, the orientation of a three-component borehole seismometer may be determined by comparison with a reference instrument at the surface. The mathematical problem can be formulated as follows: for each component  $y_i$  of the borehole seismometer find a set of three directional coefficients  $a_{i1}$ ,  $a_{i2}$ ,  $a_{i3}$  so that the output signal  $y_i$  is best represented by  $y_i = a_{i1} x_1 + a_{i2} x_2 + a_{i3} x_3$  in a least-squares sense, where  $x_1$ ,  $x_2$ ,  $x_3$  are the output signals of the three components of the reference sensor. Almost any seismic signal that is recorded with a good signal-to-noise ratio can be used as a test signal. Instrumental responses must be normalized (deconvolved to a common frequency response) and an additional band-pass filtration is recommended. The 3\*3 matrix  $A = (a_{ik})$  contains information both on the orientation and on the orthogonality of the borehole sensor (assuming proper orientation and orthogonality of the reference sensor). The x and y components can also be interchanged in the formulation of the problem; one then obtains the inverse matrix that is needed to correct the borehole signals. We offer the **linreg3** software (section 5.8, **linregress** folder) for calculating the  $a_{ik}$  coefficients. Commercial packages for linear algebra like MATLAB also offer convenient solutions.

### 5.6.8 Calibration on a shake table

Using a shake table is the most direct way of obtaining an absolute calibration. In practice, however, precision is usually poor outside a frequency band roughly from 0.5 to 5 Hz. At higher frequencies, a shake table loaded with a broadband seismometer may develop parasitic resonances, and inertial forces may cause undesired rotations. At low frequencies, the maximum displacement and thus the signal-to-noise ratio may be insufficient, and the motion may be non-uniform due to friction or roughness in the bearings. Still worse, most shake tables do not produce a purely translational motion but also some tilt. Gravity is then coupled into the seismic signal. Its relative contribution increases with the square of the signal period and causes an intolerable error in the horizontal components at long periods. One might think that a tilt of 10  $\mu$ rad per mm of linear motion should not matter; however, at periods longer than 20 s, such a tilt will cause a larger output signal than the linear motion. At a period of 1 s, the effect of the same tilt would be negligible. Long-period measurements on a horizontal shake table, if possible at all, require extreme care.

Electromagnetic shake tables may have large stray fields. They can be picked up by electromagnetic transducers or electronic circuits in the sensor so strongly that no calibration is possible at any frequency.

Although most calibration methods mentioned in the previous section are applicable on a shake table, the preferred method is to record both the motion of the table (as measured with a displacement transducer) and the output signal of the seismometer, and to analyze these signals by linear modeling with **calex** (section 5.8) or equivalent software. Depending on the definition of active and passive parameters, one might determine only the absolute gain (responsivity, generator constant) or any number of additional parameters of the frequency response. **calex** permits the elimination of tilt effects from a shake-table calibration, under the assumption that the tilt is proportional to the displacement.

### 5.6.9 Calibration by stepwise motion

The movable tables of machine tools like lathes and milling machines, and of mechanical balances, can replace a shake table for the absolute calibration of seismometers. Also, a portable “step table” for seismometer calibration is now commercially available. The idea is to place the seismometer on the table, let it come to equilibrium, then move the table by a known amount and let it rest again. The apparent motion of the frame can then be calculated by inverse filtration of the output signal and compared with the known mechanical displacement. Since the calculation involves triple integrations, offset and drift must be carefully removed from the seismic trace. The main contribution to drift in the apparent horizontal velocity comes from tilt associated with the motion of the table. With the method subsequently described, it is possible to separate the contributions of displacement and tilt from each other so that the displacement can be reconstructed with good accuracy. This method of calibration is most convenient because it uses only normal workshop equipment. The inherent precision of machine tools and the use of relatively large motions eliminate the difficulty of measuring small mechanical displacements. A FORTRAN program **dispcal** is available for the evaluation (section 5.8).

The precision of the method depends on avoiding two main sources of error:

1 - Restoring ground displacement from the seismic signal (a process of inverse filtration) is uncritical for broadband seismometers but requires a precise knowledge of the transfer function for short-period seismometers. Instruments with unstable parameters (such as electromagnetic seismometers) must be electrically calibrated while installed on the test table. However, once the response is known, the restitution of absolute ground motion is no problem even for a geophone with a free period of 0.1 s.

2 - The effect of tilt can only be removed from the displacement signal when the motion is sudden and short. The tilt is unknown during the motion, and since it is equivalent to an acceleration, it produces an unknown offset in the displacement trace that cannot be distinguished from a true displacement. The magnitude of this error signal can however be estimated from the apparent velocity observed when the true motion has ended. In contrast, static tilt before and after the motion produces linear trends in the velocity, which are easily removed.

The computational evaluation consists in the following major steps (Fig. 5.26):

- 1) the trace is de-convolved with the velocity transfer function of the seismometer.
- 2) the trace is piecewise de-trended so that it is close to zero in the motion-free intervals.  
Interpolated trends are removed from the interval of motion.
- 3) the trace is integrated to represent displacement
- 4) the displacement steps are measured and compared to the actual motion.

**Fig. 5.26** Absolute mechanical calibration of an STS1-BB (20s) seismometer on the table of a milling machine, evaluated with DISPCAL. The table was manually moved in 14 steps of 2 mm each (one full turn of the dial at a time). Traces from top to bottom: recorded BB output signal; restored and de-trended frame velocity; restored frame displacement.

In principle, a single step-like displacement is all that is needed. However, the experiment takes so little time that it is convenient to produce a dozen or more equal steps, average the results, and do some error statistics. On a milling machine or lathe, it is recommended to install a mechanical device that stops the motion after each full turn of the spindle. On a balance, the table is repeatedly moved from stop to stop. The displacement may be measured with a micrometer dial or determined from the motion of the beam (Fig. 5.27).

**Fig. 5.27** Calibrating a vertical seismometer on a mechanical balance. When a mass of  $w_1$  grams at some point X near the end of the beam is in balance with  $w_2$  grams on the table or compensated with a corresponding shift of the sliding weight, then the motion of the table is by a factor  $w_1/w_2$  smaller than the motion at X.

From the mutual agreement between different experiments, and from the comparison with shake-table calibrations, the absolute accuracy is estimated to be better than 1%.

EX 5.2 by J. Bribach is an exercise for estimating seismometer parameters by step function.

### 5.6.10 Calibration with tilt

Accelerometers can be statically calibrated on a tilt table. A step table with an additional tilt platform can likewise be used. Starting from a horizontal position, the fraction of gravity coupled into the sensitive axis equals the sine of the tilt angle. (A tilt table is not required for accelerometers with an operating range exceeding  $\pm 1g$ ; these are simply turned upside down.). Force-balance seismometers normally have a mass-position output which is a slowly responding acceleration output. With some patience, this output can likewise be calibrated on a tilt table; the small static tilt range of sensitive broadband seismometers, however, may be inconvenient. The transducer constant of the calibration coil is then obtained by sending a direct current through it and comparing its effect with the tilt calibration. Finally, by exciting the coil with a sine wave whose acceleration equivalent is now known, the absolute calibration of the broadband output is obtained. The method is not explained in more detail here because we propose a simpler method. Anyway, seismometers of the homogeneous-triaxial type cannot be calibrated with static tilt because they do not have X, Y, Z mass-position signals.

The method that we propose (for horizontal components only; program **tiltcal**, section 5.8) is similar to what was described under 5.6.10, but this time we calibrate the seismometer with known steps of tilt, and evaluate the recorded output signal for acceleration rather than displacement.

This is simple: the difference between the drift rates of the de-convolved velocity trace before and after the step equals the tilt-induced acceleration. No baseline interpolation is required. If a tilt platform is not available, one can also tilt the seismometer with a lever under one of its feet, or by pulling out a strip of shim stock. In order to improve the signal-to-noise ratio, it is possible to use a tilt step that exceeds the static operating range of the seismometer. One then has to monitor the output signal and reverse the tilt before the output signal reaches the clipping level.

## 5.7 Testing for non-linear distortions

As we have seen in section 5.2.1, a linear system does not change the waveform of a sinewave. A system that does is said to produce nonlinear distortions. (Linear distortions are those resulting from the frequency-dependent response of a linear system; they affect only waveforms that are not sinusoidal.) A nonlinear system generates spurious signals with frequencies that are multiples (harmonics), sums and differences of the original frequencies. Other than in audio equipment where the high-frequency distortions are most annoying, in seismic recording the distortion (intermodulation) products with low frequencies are most obnoxious because they can cause large errors when signals are inversely filtered or integrated in an attempt to reconstruct ground displacement.

Testing a seismometer for nonlinear distortions, and reporting results properly, is a complex task and one must often be satisfied with a partial answer. Distortions can originate in the mechanical receiver, in the transducers, and in electronic circuits. While for a linear system a current through the calibration coil is unconditionally equivalent to a mechanical acceleration (see 5.2.7), with respect to nonlinear distortion it is not. An electrically linear sensor can still be nonlinear for a seismic input signal. An electrically nonlinear sensor is however unlikely to respond linearly to ground motion, so electrical tests are not useless; but such tests essentially probe the feedback circuit, not the transducers or the mechanical receiver. A serious test for nonlinear distortions therefore requires a nearly sinusoidal mechanical input from a shake table.

Fortunately it turns out that the shake table needs not be more linear than the seismometer if we use the right method. Two methods are available:

1 – The classical two-tone test. The shake table is excited with two superimposed sinewaves of nearly the same frequency, such as 1.00 and 1.02 Hz. Nonlinearity, either of the table or of the sensor, will generate a spurious output signal at the difference (beat) frequency  $\omega_B$ , here 0.02 Hz. It can be separated from the 1 Hz signals by low-pass filtration or Fourier analysis. The contributions from the table and from the seismometer can be separated from each other by repeating the experiment at different beat frequencies (0.05 Hz, 0.02 Hz, 0.01 Hz or even lower). Nonlinearity of the table motion causes an offset of the average table position; the amplitude of the equivalent acceleration at the beat frequency is proportional to  $\omega_B^2$ . Nonlinearity in the seismometer causes a spurious acceleration signal whose amplitude is independent of  $\omega_B$ . Thus, at sufficiently low beat frequencies, seismometer nonlinearity will always predominate. (Whether we see the beat signal or not depends, of course, on the noise level.) Other signal frequencies (2.00 and 2.02 Hz, 5.00 and 5.02 Hz etc.) should also be used because the distortion level depends strongly on the signal frequency.

2 – Linear modeling. The table is excited with a sinewave or a sweep signal. Its motion is measured with a displacement transducer (which may already be there as part of the control electronics) and recorded together with the output signal. With **calex** or an equivalent method, we can then compute a synthetic output signal and compare it to the observed one. The difference (residual, misfit) is composed of seismic noise, nonlinear distortions, and an error signal due to imperfect modeling. Nonlinear distortions can be distinguished from the other contributions because in this experiment their most prominent frequency is twice the input frequency. Although these distortions may not be harmful by themselves, we know that they are always associated with the low-frequency distortions for which the two-tone test was designed. If we want to see these directly, we can duplicate the two-tone test with linear modeling by using a two-tone input signal.

The combination of both methods – linear modeling followed by low-pass filtration of the residual – is especially suitable to detect low-frequency distortions (intermodulation). Modern broadband seismometers typically have mechanical intermodulation ratios around -100 dB in the same units. Electrical intermodulation ratios are typically around -130 dB in the same units. In other units, the dependence on the signal and beat frequencies is normally so strong that it would not be meaningful to quote a typical value. The test procedures outlined here are described in more detail in an USGS Open-File Report (Hutt et al. 2009, p. 21-24; <http://pubs.usgs.gov/of/2009/1295/>).

## 5.8 Free Software

All software mentioned in the text and printed in bold black letters can be downloaded from [HERE](#) or from the summary listing *Download Programs & Files* (see NMSOP-2 content **Overview** on the cover page). A still larger body of software for data analysis, instrument testing, generating synthetic signals, and tutorial purposes is found at

<http://www.geophys.uni-stuttgart.de/~erhard/downloads/>  
<http://www.software-for-seismometry.de/>

Test data are supplied where appropriate. Use the “software overview” on the given websites to select what you need, go to the appropriate software folder, and read the “program descriptions” for details.

A supplementary **calibrat** system, offered by J. Bribach, can also be downloaded via the summary listing. It comprises the programs **response**, **caliseis** and **seisfilt**. A short description of these programs is given in PD 5.1.

## Acknowledgments

This is a revised version (2009 and 2010) of Chapter 5 (Wielandt, 2002a) in the printed first edition of the IASPEI New Manual of Seismological Observatory Practice (NMSOP). For complete citation of this first edition see Bormann, P. (ed.) (2002) under References.

Three careful reviews by the Editor of the NMSOP, Peter Bormann, and suggestions by Axel Plešinger and Jens Havskov have significantly improved the clarity and completeness of this text. A shorter version (Wielandt, 2002b), with some advanced topics added, appeared in part A of the IASPEI International Handbook of Earthquake and Engineering Seismology, ed. W. H. Lee et al. (2002), ISBN-13: 978-0-12-440652-0, ISBN-10: 0-12-440652-1.

## Introduction

These data sheets describe some widely used broadband seismic sensors, and a few other sensors that are new or have an interesting principle of operation. We present them as examples of a format in which seismic sensors might be uniformly described; our choice does not imply any recommendation for or against a specific instrument.

Manufacturers' specifications, especially for complex characteristics such as sensitivity and dynamic range, are sometimes realistic, sometimes optimistic, and sometimes useless. Some widely used broadband seismometers have recently been tested for noise at the USGS Albuquerque Seismological Lab. We have used these data wherever possible (see Ringler and Hutt, 2010). But independent information is not always available, and then the information from the manufacturer's data sheet must somehow be translated into our scheme. We have done this to the best of our knowledge, but errors and even a subjective bias cannot be ruled out.

Noise specifications are among the most important for the seismologist and among the most difficult for the manufacturer. Seismometers are typically produced in a noisy industrial environment, so most manufacturers cannot easily test their products for self-noise. New instruments often show transient disturbances which may disappear within a few months in a permanent installation but interfere with noise tests immediately after production. In order to ascertain the noise specifications, lengthy tests of each instrument at a remote quiet site would be required, and a substantial portion of the production might have to go to scrap. Customers are not willing to pay for this, and consequently manufacturers do not guarantee the noise specifications. Nevertheless, depending on details of the production process and on the time allocated to testing, some manufacturers turn out a higher proportion of faultless instruments than others. The user should be aware of this problem, but we cannot extrapolate it from the past into the future, and cannot quantify it in our data sheets. Also, part of what appears to be self-noise is often of environmental origin, and depends on undocumented details of the site and the test setup.

The "category" information in the data sheets may require some explanation. The term "broadband" (BB) is commonly used for seismometers that have a flat response to velocity from short periods to at least 30 seconds. The nominal bandwidth is however not what really matters. Instruments should be named after the frequency band in which they deliver useful signals. We will therefore use the term "broadband" for instruments that can be used throughout the classical short-period and long-period bands, and "very broadband" or VBB for instruments suitable to record free oscillations of the Earth. "Symmetric triaxial" means that the sensitive axes of the mechanical sensors are 54.7 degrees from vertical (Galperin 1955 and 1977), such as in the STS2 and the Trilliums.

Below, the sensor data sheets are alphabetically ordered. Another overview over broadband seismometers is found at [http://sismic.iec.cat/orfeus/instrumentation/vault\\_sensors.html](http://sismic.iec.cat/orfeus/instrumentation/vault_sensors.html).

| Typical installation | observatory, vault, and field use                                                                                                                                                                                |
| Data sheet           | <a href="http://www.guralp.com/products/3T/">http://www.guralp.com/products/3T/</a>                                                                                                                              |
| Remarks              | Tight thermal shielding recommended. Until recently the CMG-3T was one of the two most widely used broadband seismometers (the other one being the STS-2). The noise data are from the borehole version CMG-3TB. |

\* based on Ringler and Hutt (2010). Resolution above 10 Hz is extrapolated; data from the borehole version.

| Remarks              | This is a modern and popular strong-motion sensor. Its large dynamic range overlaps considerably with that of high-sensitivity seismometers, making it possible to record microearthquakes and teleseisms with this instrument. |

| Remarks              | A widely used high-performance, short-period seismometer. For very quiet sites, model GS-13 is the best choice. It resolves high-frequency signals much better than any broadband-feedback seismometer. See publications by Riedesel et al. (1990) and by Rodgers (1993 and 1994) for information on preamplifier design and noise. |

\* based on circuit analysis with op-amp LT1007 as a preamplifier. Low-noise model may be inaccurate above 10 Hz.

| Remarks              | A very small and rugged three-component, short-period, active seismometer. The sensor is a commercial 4.5 Hz geophone whose response is electronically extended by a negative damping resistance (a form of negative feedback). Not as sensitive as larger seismometers but good enough where ground noise is not extremely low. A single-component version Le-1d is also available. Higher performance is offered by the Le-3d/5s and Le-3d/20s. |

| Remarks              | A small and rugged three-component, medium-period, active seismometer. The sensor is a commercial 2 Hz geophone whose response is electronically extended by a negative damping resistance (a form of negative feedback). Not as sensitive as larger seismometers but good enough where ground noise is not extremely low. |

| Remarks              | A still widely used short-period seismometer for field work. See publications by Riedesel et al. (BSSA <b>80</b> ,6) and by Rodgers (BSSA <b>83</b> ,2 and <b>84</b> ,1) for information on preamplifier design and noise.<br>The Mark L4-3D is out of production but OYO-Geospace offers a comparable three-component package, the “Seis-Monitor” based on the GS-1 geophone. |

\* based on circuit analysis with op-amp LT1007 as a preamplifier. Low-noise model may be inaccurate above 10 Hz.

|                      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |

| Remarks              | An unconventional sensor. The horizontals are essentially circular-tube tiltmeters where the flow of an electrolyte through a platinum mesh is measured using the MET effect (molecular-electronic transfer, also used in the “solion” transducer). The vertical sensor supports a column of electrolyte in a vertical tube with a membrane and a spring. These sensors have extremely low power consumption, are very rugged, need not be locked or leveled; they simply start working after power-on. Their performance in other respects is however inferior to force-balance sensors. |

| Remarks              | A very good VBB sensor, in the free-mode band comparable to KS-1 and CMG-3TB according to Ringler & Hutt, 2010. |

\* based on Ringler and Hutt (2010). Resolution above 10 Hz is extrapolated.

| Remarks              | Operated under partial vacuum; no electronics inside the sensor. This seismometer made the very-broad-band velocity response popular, and is the only seismometer to resolve minimum ground noise throughout the long-period seismic band. (Some say it defines the low-noise model.)<br>The STS1 is no longer manufactured by Streckeisen AG but Metrozet LLC (USA) have developed a modern, remotely controllable replacement for the feedback electronics and a modified mechanical sensor. The new system has the excellent low-frequency resolution of the original STS-1 but is easier to install and maintain. |

\* based on Ringler and Hutt (2010). Resolution above 10 Hz is extrapolated.

| Remarks              | <p>Tightly-fitting thermal isolation required for optimum performance. Until recently, the STS-2 was one of the two most widely used VBB instruments (the other being the CMG3). Three versions (generations) of the internal electronics exist. Production ended in 2010.</p> <p>The successor model STS 2.5 has the same housing but completely redesigned mechanical sensors and electronics, and can be remotely controlled with a laptop computer. Its performance is similar to that of the third-generation STS-2.</p> |                                |

<sup>1</sup> first generation, <sup>3</sup> third-generation, high-gain STS-2, based on Ringler and Hutt 2010. Resolution above 10 Hz is extrapolated.

| Remote control       | mass lock, centering, calibration, short-period mode                                                                                                                                                                                                                                                                                                    |
| Remote diagnostic    | mass position, state-of health parameters including temperature, internal humidity, tilt, serial number, supply voltage                                                                                                                                                                                                                                 |
| Accessories          | a "Host Box" with power conditioning and LED status indicators is included.                                                                                                                                                                                                                                                                             |
| Typical installation | Observatory, vault. Needs additional protection in humid or dirty environments.                                                                                                                                                                                                                                                                         |
| Data Sheet           | <a href="http://www.kinematics.com/uploads/PDFs/STS-2_5.pdf">http://www.kinematics.com/uploads/PDFs/STS-2_5.pdf</a>                                                                                                                                                                                                                                     |
| Remarks              | Tightly-fitting thermal isolation required for optimum performance. The STS 2.5 has the same housing as the STS-2 but completely redesigned mechanical sensors and electronics. Remote control with a laptop computer. The STS 2.5 has not yet been extensively tested but appears to perform equally or slightly better than a third-generation STS-2. |

<sup>3</sup> self-noise data are from a third-generation, high-gain STS2, based on Ringler and Hutt (2010). Resolution above 10 Hz is extrapolated.

## 1 Aim

The exercise aims at making you familiar with the easy way of construction of a BODE-diagram which displays the transfer function of a given device as a plot of logarithmic amplitude  $A$  and of linear phase shift  $\phi$  versus logarithmic frequency  $f$  (or period  $1/f$ ). Its advantage is that response curves are approximated by straight lines (see IS 5.2). The main features are:

- any Pole in the transfer function generates an amplitude decay proportional to frequency  $f$  (20 dB per decade or 6 dB per octave) and a phase shift  $\phi$  of  $-90^\circ$ ;
- any Zero causes a slope of 1:1 too and a phase shift of  $+90^\circ$ ;
- corner frequencies (e.g., of filters) correspond to the point of intersection of two straight lines.

All stages of a signal-transfer chain can thus be constructed component-wise, one after the other. It is recommended to decompose all functions into parts of 1<sup>st</sup> or 2<sup>nd</sup> order. One gets the complete transfer function by multiplying these individual functions. In both the logarithmic amplitude scale and the linear phase scale this means adding the related individual curves.

## 2 Tasks

**Task 1:** Plot the BODE-diagrams (amplitude only) of the following seismograph components:

### Seismometer

|                     |                             |
|---------------------|-----------------------------|
| Transducer Constant | $G_S = 15.915 \text{ Vs/m}$ |
| Natural Period      | $T_S = 5 \text{ s}$         |
| Attenuation         | $D_S = 0.707$               |

### HIGH Pass HP1 (1<sup>st</sup> order)

|                  |                            |
|------------------|----------------------------|
| Magnification    | $A_{H1} = 3$               |
| Corner Frequency | $f_{H1} = 0.01 \text{ Hz}$ |

### LOW Pass LP1 (1<sup>st</sup> order)

|                  |                           |
|------------------|---------------------------|
| Magnification    | $A_{L1} = 5$              |
| Corner Frequency | $f_{L1} = 0.2 \text{ Hz}$ |

### LOW Pass LP2 (2<sup>nd</sup> order)

|                  |                          |
|------------------|--------------------------|
| Magnification    | $A_{L2} = 2$             |
| Corner Frequency | $f_{L2} = 10 \text{ Hz}$ |
| Attenuation      | $D_{L2} = 0.707$         |

**Task 2:** Plot the overall amplitude response of the system approximated by straight lines on double logarithmic paper (see Figure 1).

**Figure 1**

### 3 Solution

The solution to this exercise is given in Figure 2 below.

**Figure 2** Overall BODE-diagram (solid curve) for the seismograph amplitude response. It results from the logarithmic addition of the BODE-diagrams of all individual components given in Task 1.

| Title   | Estimating seismometer parameters by step function (STEP)                                                                                                                                                |

## 1 Aim

To determine the response of a seismometer system in the time domain to a *STEP function* input. Applying a step impulse to a seismometer allows to derive the main seismometer parameters by analysing the generated time series. In the absence of expensive calibration equipment (e.g., shake table) or in the case of sealed seismometers this simple method is very suitable and can also be used under field conditions.

## 2 Procedures and relationships

### 2.1 Applying STEPs to the seismometer

Applying steps is the oldest calibration method in seismology. Teupser (1962) describes three main types:

- a) pulling a thin block (thickness max. 0.01 mm) off the seismometer bottom;
- b) applying a heavy weight upon the seismometer platform;
- c) applying a constant current to the coil of an electrodynamical system (if available; for driving current see EX 5.3: Seismometer calibration by harmonic drive).

Because a) is the roughest method one should use it for field or for portable seismometers only and never for sensitive station sensors. In case a) and b) the seismometer mass will return to the former position after deflection, in case c) the seismometer mass will move to an offset position which will depend on the applied current. To ensure linearity the mass deflection - or the seismometer displacement - should not exceed several 100 micrometers.

### 2.2 Evaluating STEP-transition time series

#### 2.2.1 All types of seismometers ( $D_S < 0.5$ )

Figure 1 shows the time series of a low-damped seismometer ( $D_S = 0.1$ ). The time section A represents the time from the moment of step input up to the transition to a real harmonic movement of the mass. The moment of step causes odd signals. Mechanical application of a step impulse generates additional vibrations because of hitting effects. An electrical step can induce an electrical pulse if the calibration coil and the signal coil are mounted to the same core (the so-called transformer effect). Therefore the analysis of the generated time series should start only beyond section A with:

**Figure 1** Response of a low-damped seismometer to a step pulse.

**First step:** Measuring of the period and damping of the time series.

The period  $T$  should be measured by averaging over as many cycles as possible (10 or more) to get an accuracy better than 99%.

**Note!** The measured period is larger than the natural period because of the seismometer damping.

The damping  $D$  is calculated from the equation

$$D = \frac{1}{\sqrt{\left(\frac{(N-1)\pi}{\ln(a_1/a_N)}\right)^2 + 1}} \quad (1)$$

with  $a_1$  as the double amplitude between the first two oscillation peaks ( $p_1$  and  $p_2$ ) and  $a_N$  as the double amplitude between the peaks ( $p_N$  and  $p_{N+1}$ ).  $N$  should be selected so as to get an  $a_N \approx 0.2 \dots 0.4 a_1$ .

**Second step:** Estimation of the natural period  $T_S$  of the seismometer.

If possible switch off all external attenuators (e.g., resistors) to decrease the measuring error. For example: with a damping  $D = 0.2$  the measured period is  $T = 1.02 T_S$ .

The natural period of the seismometer is

$$T_S = T \sqrt{1 - D^2}. \quad (2)$$

### 2.2.2 Electro-dynamical system (moving coil)

The electro-dynamical constant (or generator constant)  $G_S$  of a moving coil system can also be estimated by step transition via its relation to damping  $D$ . The complete seismometer damping  $D_S$  is

$$D_S = D_{S0} + D_G \quad (3)$$

with  $D_{S0}$  as the natural damping of the seismometer (mostly mechanical effects), and with  $D_G$  as the moving coil damping. The latter is caused by an external resistor  $R_a$  shorting the coil (electromagnetic force), i.e.:

$$D_G = \frac{G_S^2 T_S}{4\pi m_S (R_a + R_S)} \quad (4)$$

Except for  $R_a$  and  $T_S$  all other parameters in Equation (4) are documented by the manufacturer and will not change over time. While for pendulum seismometers usually the parameters

- |                      |                         |
|----------------------|-------------------------|
| - $K_S$ [ $kg.m^2$ ] | inertial moment         |
| - $l_0$ [ $m$ ]      | reduced pendulum length |

are given instead of  $m_S$  one gets for geophone systems

- |                                   |                  |
|-----------------------------------|------------------|
| - $m_S$ [ $kg$ ] = $K_S l_0^{-2}$ | seismic mass and |
| - $R_S$ [ $Ohms$ ]                | coil resistance. |

**Note!** When measuring coil resistance don't forget to lock the seismometer.

The evaluation again starts as above with: measuring of the period and damping of the time series as the first step and the estimation of the seismometer's natural period  $T_S$  as the second step.

This is followed by:

**Third step:** Estimation of the seismometer's natural damping  $D_{S0}$ .

The external damping resistor must be removed (open circuit). Then we get, similarly to (1),

$$D_{S0} = \frac{1}{\sqrt{\left(\frac{(N-1)\pi}{\ln(a_1 / a_N)}\right)^2 + 1}} \quad (5)$$

**Fourth step:** External damping.

The external resistor must be set to a value that causes a damping down to 20 - 50% per period. Then we measure the neighbouring amplitudes  $a_1$  (between  $p_1$  and  $p_2$ ) and  $a_2$  (between  $p_2$  and  $p_3$ ;  $p_2$  is used twice to reduce measuring error) and get

$$G_S \quad [\text{Vs/m}] \quad = \quad \sqrt{(D_S - D_{S0}) \frac{4\pi}{T_S} m_S (R_a + R_S)}.$$

(6)

This constant can also be used when calibrating a system by harmonic drive.

**Note!** For pendulum seismometers there are different notations for this constant:

- 1) force/current  $[\text{N/A}] = [\text{Vs/m}]$  and
- 2) torque/current  $[\text{Nm/A}] = [\text{Vs}]$

They are related via the reduced pendulum length  $l_0$  as follows:

$$G_{S1} [V_S] = G_{S2} [V_S / m] \cdot l_0 [m]. \quad (7)$$

### 3 Data: Application to a specific seismometer

Below a typical seismometer parameter list is given.

#### Mechanical constants:

|                            |          |                          |
|----------------------------|----------|--------------------------|
| Natural period             | $T_S$    | ..... s                  |
| Open damping (Attenuation) | $D_{S0}$ | .....                    |
| Reduced pendulum length    | $l_0$    | 0.0785 m                 |
| Inertial moment            | $K_S$    | 0.0201 kg m <sup>2</sup> |
| Seismic mass               | $m_S$    | ..... kg                 |

#### Transducer constants 1 (signal coil):

|                           |          |                         |
|---------------------------|----------|-------------------------|
| Coil resistance           | $R_{S1}$ | 6030 $\Omega$           |
| Electrodynamical constant | $G_{S1}$ | ..... V <sub>S</sub> /m |

#### Transducer constants 2 (calibration coil):

|                           |          |                         |
|---------------------------|----------|-------------------------|
| Coil resistance           | $R_{S2}$ | 835 $\Omega$            |
| Electrodynamical constant | $G_{S2}$ | ..... V <sub>S</sub> /m |

### 4 Tasks

#### Task 1:

Mark those seismometer parameters which are absolutely necessary for calculating the seismometer response curve (BODE-diagram).

#### Task 2:

Complete the list above by analysing the related time series plots in Figure 2a - c.

#### Task 3:

Calculate the current  $I_C$  through the calibration coil which is necessary to deflect the seismometer mass by 1  $\mu\text{m}$  at a frequency  $f = 1 \text{ Hz}$  (see EX 5.3: Seismometer calibration by harmonic drive).

**Figure 2a** Seismometer step response: open circuit.

**Figure 2b** Seismometer step response: signal coil with external resistor  $R_a = 67 \text{ k}\Omega$ .

**Figure 2c** Seismometer step response: calibration coil with external resistor  $R_a = 1 \text{ k}\Omega$ .

## 5 Solutions

### Task 1:

Seismometer parameters absolutely necessary for calculating the seismometer response curve are marked by an asterisk (\*) in the listing below (see Task 2). Additionally required are the *seismometer damping*, consisting of the *open damping* plus the *external* (here: *electrodynamical*) damping.

### Task 2:

Completed list of seismometer parameter:

#### Mechanical constant:

|                            |          |   |                          |     |
|----------------------------|----------|---|--------------------------|-----|
| Natural Period             | $T_{S0}$ | = | 1.617 s                  | (*) |
| Open damping (attenuation) | $D_{S0}$ | = | 0.0102                   |     |
| Reduced Pendulum Length    | $l_0$    | = | 0.0785 m                 |     |
| Inertial Moment            | $K_S$    | = | 0.0201 kg m <sup>2</sup> |     |
| Seismic Mass               | $m_S$    | = | 3.262 kg                 |     |

#### Transducer constants 1 (signal coil):

|                           |          |   |               |     |
|---------------------------|----------|---|---------------|-----|
| Coil Resistance           | $R_{S1}$ | = | 6030 $\Omega$ |     |
| Electrodynamical Constant | $G_{S1}$ | = | 571.1 Vs/m    | (*) |

#### Transducer constants 2 (calibration coil):

|                           |          |   |              |  |
|---------------------------|----------|---|--------------|--|
| Coil Resistance           | $R_{S2}$ | = | 835 $\Omega$ |  |
| Electrodynamical Constant | $G_{S2}$ | = | 67.97 Vs/m   |  |

### Task 3:

In order to deflect the seismometer mass for  $1\text{ }\mu\text{m}$ , a current of  $I_C = 0.12\text{ mA}$  has to be driven through the calibration coil.

If the seismometer possesses an auxiliary magnet and coil assembly, the calibration can be carried out with the aid of an electric current. According to Eq. (5.25) in Chapter 5 and related discussion a current  $i_s$  acts in the same way as a ground acceleration

$$\frac{d^2 x_e}{dt^2} = \frac{G_{s2} l_0^2}{K_s} i_s . \quad (1)$$

where  $G_{s2}$  is the electrodynamic constant of the auxiliary coil (given in [Vs/m]). For other constants see EX 5.2 *Estimating seismometer parameters by STEP function*. It corresponds to a harmonic drive of frequency  $f$  with an equivalent ground displacement

$$x_e = \frac{G_{s2} l_0^2}{4\pi^2 f^2 K_s} i_s . \quad (2)$$

For a translational seismometer, for example a geophone, with seismic mass  $m_s$ , the equivalent seismic displacement is

$$x_e = \frac{G_{s2}}{4\pi^2 f^2 m_s} i_s . \quad (3)$$

Since the output voltage of a geophone with an electromagnetic transducer is

$$E_s = G_{s1} \frac{dz}{dt} , \quad (4)$$

where  $z$  is the displacement of the seismic mass,  $G_{s1}$  is the electrodynamic constant of the signal coil and  $f_s$  the natural frequency, one obtains for a harmonic excitation

$$E_s = \frac{G_{s1} G_{s2} f}{2\pi m_s \sqrt{(f^2 - f_s^2)^2 + 4D_s^2 f^2 f_s^2}} . \quad (5)$$

Changing the frequency of the exciting current the output voltage attains a maximum at  $f = f_s$ . This can be used to determine the natural frequency and the damping using an oscilloscope.

| Title   | Seismometer calibration with program CALEX                                                                                                                                   |

| Version | October 2010; DOI: 10.2312/GFZ.NMSOP-2_EX_5.4                                                                                                                                |

## 1 Software and Data

It is recommended to download the latest versions of the **calex** and **winplot** software from either [www.software-for-seismometry.de](http://www.software-for-seismometry.de) or by right mouse click on these program names in the NMSOP-2 content overview folder *Download Programs & Files*.

Two pairs of input ("eing") and output ("ausg") signals are available. They are shown in Figures 1 and 2; one set is from a broadband seismometer and the other from a short-period geophone. File names may differ depending on the version.

**Figure 1** The input signal into the calibration coil (eing) is a "sweep", a sine-wave whose frequency is automatically tuned from about 2 s to 50 s. It is used for calibration of a 20-sec STS1 seismometer. The second and third traces show the output (ausg) signal and the best fitting synthetics (synt), respectively. The lowermost trace is the residual signal (ausg - synt = rest).

**Figure 2** The input signal is a square wave. It is used for calibration of an undamped 10 Hz geophone in a half-bridge. Note that the input signal appears in the output by coupling through the coil resistance. This would not be the case for a seismic input signal and therefore must not be interpreted as part of the transfer function.

## 2 Tasks

- 1 - Plot the signals on the screen and get an idea of the time scale, of the free period and damping of the sensor, and of the type of response (high-pass, band-pass, low-pass?). You will also need an estimate of polarity and gain between input and output. Compare what you see in the plot to your knowledge of the general properties of seismometer transfer functions.
- 2 - Set up the **calex.par** file for each experiment, as specified in the program description. A sample file is listed there.
- 3 - Run **calex** to determine the exact instrumental constants. Inspect the residual signal and determine its magnitude relative to the output signal (the misfit). Is the misfit caused by improper parametrization of the transfer function, by seismic or environmental noise, or by nonlinear behavior of the sensor? In the latter case, can you guess what the problem might be?
- 4 - Run **calex** again with deliberately offset start parameters, to see if their choice (within a reasonable range) is critical. You may also restrict the analysis to a smaller time window within the record and see if you get different results.

### 3 Solutions

Please read the Program Description for the **calex** and **winplot** routines before continuing. If you use an older program version, it may be necessary to copy 'eing1' onto 'eing' (input signal) and 'ausg1' onto 'ausg' (output signal).

Tasks 1 and 2, first signal: On a Windows PC, you may use the 'winplot' routine for plotting the seismograms. To display the two signals, you have to prepare a small parameter file named winplot.par containing parameters and file names (as specified in the program description of winplot). Under LINUX, use your own plotting routine.

An electromagnetic seismometer, or a broadband-velocity sensor, acts as a band-pass filter for ground accelerations or calibration signals. It gives a maximum response when the signal period equals the free period of the system. By inspecting of the ausg signal, you will recognize that this is in fact a band-pass response, and the free period is around 20 s. The damping is more difficult to estimate, but since the resonance is not sharp, damping must be considerable. Knowing that  $1/\sqrt{2}$  or about 0.7 is a standard value for seismometers, you should start the inversion with this value. The gain between eing and ausg is around unity and the signals have the same phase at the resonance, so the gain parameter in calex.par may be set to 1.

Second signal: copy the data files as above if necessary, and inspect the 'ausg' file. Use the "sub" parameter to remove the resistive component of the output signal (see program description). The free period is obviously around 0.1 s. The damping may be estimated using formula 5.32 (section 5.6.5) of the NMSOP; it is similar to the previous case. The gain between eing and ausg is again near unity and positive.

Task 3, first signal: you should approximately get 19.7 s for the free period, 0.72 for the damping, 1.36 for the gain, 10 ms for the delay, and a rms residual below 0.003. Change the second parameter in 'winplot.par' to 4 and add the file names 'synt' and 'rest'. (New versions of **calex** do this automatically.) Note the transient disturbance in the 'rest' signal at the end of the first minute, which was caused by a person entering the room. Its effect on the result is quite small.

Second signal: the period is 0.102 s, the damping 0.65, the gain is 1.17, and about 48% of the input signal are present in the output signal. The rms residual is again below 0.003. Note the asymmetry in the residual between upgoing and downgoing steps. What you see is mass-position dependent, nonlinear behaviour of the geophone; this is not a bad geophone, but it's no force-balance sensor. You may also notice the small wiggles before and after each step of the input and output signals. (Zoom into a time window with 'seipl02' for better resolution.) The wiggles are not present in the analog signals but are generated by the decimation filters of the digital recorder. Since these filters affect both signals, they don't appear in the transfer function.

Task 4: the results should be nearly independent of the start parameters and of the data window as long as the essential information is preserved in the window.

| Title   | Interpreting Poles and Zeros from SEED headers                                                                                                                               |

| Version | October 2010; DOI: 10.2312/GFZ.NMSOP-2_EX_5.5                                                                                                                                |

## 1 Aim

The complex transfer function (or the related complex frequency response) of the analog part of a seismograph is a rational function of frequency. Such functions can be specified by corner frequencies and damping constants, by polynomial coefficients, or by their poles and zeros. The latter method is chosen in the IRIS SEED data volumes. For each data channel of each station, the data header contains a list of poles and zeros of the transfer function together with some auxiliary information. IRIS supplies a software library 'evalresp' for extracting and interpreting these parameters. The exercise aims at making you familiar with interpreting poles and zeros in terms of the amplitude response versus frequency.

## 2 Task

Interpret one or more of the annexed SEED headers with respect to the analog part of the seismograph. Sketch the amplitude response for one of the stations as a Bode-diagram on double logarithmic paper. (The digital part is usually of minor interest since it is supposed to have a flat amplitude response and zero phase delay.) Does the header describe a very broadband, broadband or narrowband system? Note that the answer does not only depend on the mathematical form of the response but also on the definition of the input signal - displacement, velocity or acceleration. A broadband seismograph is supposed to have a broadband response to velocity but a broadband accelerometer has a broadband response to acceleration. Be careful with the units - some headers refer to Hertz rather than radians/sec. Check also whether the poles and zeros refer to the Laplace transform or Fourier transform. Can you guess which type of sensor is used? Are the constants nominal or were they determined from an individual calibration?

A little computer program **polzero** in BASIC can be downloaded from either [www.software-for-seismometry.de](http://www.software-for-seismometry.de) or by right mouse click on this program name in the NMSOP-2 content overview folder *Download Programs & Files*. It will do for you the numerical conversions and plot the amplitude response. Use this program to analyze some more of the SEED headers. The stations are:

KIP (Kipapa, Hawaii)  
 KONO (Kongsberg, Norway)  
 KMI (Kunming, China)  
 PFO (Pinion Flat Observatory, California)  
 XAN (Xi'an, China)

## 3 Annex

SEED headers for stations KIP, KONO, KMI, PFO and XAN

## 1 Introduction

The long-period seismograph of the now obsolete WWSSN (Worldwide Standardized Seismograph Network) consisted of a long-period electrodynamic seismometer normally tuned to a free period of 15 sec, and a long-period mirror-galvanometer with a free period around 90 sec. (In order to avoid confusion with the frequency variable  $s = j\omega$  of the Laplace transformation, we use the non-standard abbreviation „sec“ for seconds in the present subsection.) The WWSSN seismograms were recorded on photographic paper rotating on a drum. The simple design of this system gives us an opportunity to write down several equivalent forms of the transfer function explicitly. Since input and output signals can be measured as displacements, it is natural to describe the system by its displacement response. The absolute value of this response is the frequency-dependent magnification. We assume the numerical damping to be 0.6 for the seismometer and 0.9 for the galvanometer. For simplicity, we ignore the small difference between the free periods and damping constants of the physical subunits and those that appear in the transfer function of the coupled system. We further assume that the effective generator constant of the electromagnetic velocity transducer in the seismometer is 200 V per m/s, and the photographic trace is deflected by 0.3935 mm per microvolt.

## 2 Tasks

- **Write down** the transfer function for displacement as a function of the Laplace variable  $s$ , using symbolic algebra (that is, representing free period and damping by mathematical symbols, not their numerical values)
- **Write down** the formula for the “magnification curve” (amplitude response as a function of the angular frequency), using symbolic algebra
- **Represent** the magnification curve as a “Bode plot”, that is, approximate it by asymptotic straight lines in a double-logarithmic plot (as in exercise EX 5.1)
- **Determine** the poles and zeros of the transfer function in symbolic algebra, and evaluate them numerically
- **Sketch** the position of poles and zeros in the complex  $s$  plane
- **Write down** the transfer function as the ratio of two polynomials with numerical coefficients

### 3 Solution

As shown in Chapter 5, section 5.2.8, Eq.(5.23), the transfer function of an electromagnetic seismometer (input: displacement, output: voltage) is

$$H_s(s) = Es^3 / (s^2 + 2s\omega_s h_s + \omega_s^2) \quad (1)$$

where  $\omega_s = 2\pi/T_s$  is the angular eigenfrequency and  $h_s$  the numerical damping. (see EX 5.2 for a practical determination of these parameters.) The factor  $E$  is the generator constant of the electromagnetic transducer, for which we assume a value of 200 Vs/m.

The galvanometer is a second-order low-pass filter and has the transfer function

$$H_g(s) = \gamma\omega_g^2 / (s^2 + 2s\omega_g h_g + \omega_g^2) \quad (2)$$

Here  $\gamma$  is the responsivity (in meters per volt) of the galvanometer with the given coupling network and optical path. We use a value of 393.5 m/V, which gives the desired overall magnification. The overall transfer function  $H_d$  of the seismograph is obtained in our simplified treatment as the product of the factors given in Eqs. (1) and (2):

$$H_d(s) = \frac{Cs^3}{(s^2 + 2s\omega_s h_s + \omega_s^2)(s^2 + 2s\omega_g h_g + \omega_g^2)} \quad (3)$$

The numerical values of the constants are  $C = E\gamma\omega_g^2 = 383.6/\text{sec}$ ,  $2\omega_s h_s = 0.5027/\text{sec}$ ,  $\omega_s^2 = 0.1755/\text{sec}^2$ ,  $2\omega_g h_g = 0.1257/\text{sec}$ , and  $\omega_g^2 = 0.00487/\text{sec}^2$ .

As the input and output signals are displacements, the absolute value  $|H_d(s)|$  of the transfer function is simply the frequency-dependent magnification of the seismograph. The gain factor  $C$  has the physical dimension  $\text{sec}^{-1}$ , so  $H_d(s)$  is in fact a dimensionless quantity.  $C$  itself is however not the magnification of the seismograph. To obtain the magnification at the angular frequency  $\omega$ , we have to evaluate  $M(\omega) = |H_d(j\omega)|$ :

$$M(\omega) = \frac{C\omega^3}{\sqrt{(\omega_s^2 - \omega^2)^2 + 4\omega^2\omega_s^2 h_s^2} \sqrt{(\omega_g^2 - \omega^2)^2 + 4\omega^2\omega_g^2 h_g^2}} \quad (4)$$

Eq. (3) is a factorized form of the transfer function in which we still recognize the sub-units of the system. We may of course insert the numerical constants and expand the denominator into a fourth-order polynomial

$$H_d(s) = 383.6s^3 / (s^4 + 0.6283s^3 + 0.2435s^2 + 0.0245s + 0.000855) \quad (5)$$

but the only advantage of this form would be its shortness.

The poles and zeros of the transfer function are most easily determined from Eq. (3). We read immediately that a triple zero is present at  $s = 0$ . Each factor  $s^2 + 2s\omega_0 h + \omega_0^2$  in the denominator has the zeros

$$s_0 = \omega_0(-h \pm j\sqrt{1-h^2}) \quad \text{for } h < 1$$

$$s_0 = \omega_0(-h \pm \sqrt{h^2 - 1}) \quad \text{for } h \geq 1$$

so the poles of  $H_d(s)$  in the complex  $s$  plane are (see Figure 1):

$$s_1 = \omega_s(-h_s + j\sqrt{1-h_s^2}) = -0.2513 + 0.3351j \quad [\text{sec}^{-1}]$$

$$s_2 = \omega_s(-h_s - j\sqrt{1-h_s^2}) = -0.2513 - 0.3351j \quad [\text{sec}^{-1}]$$

$$s_3 = \omega_g(-h_g + j\sqrt{1-h_g^2}) = -0.0628 + 0.0304j \quad [\text{sec}^{-1}]$$

$$s_4 = \omega_g(-h_g - j\sqrt{1-h_g^2}) = -0.0628 - 0.0304j \quad [\text{sec}^{-1}]$$

**Figure 1** Position of the poles of the WWSSN-LP system in the complex  $s$  plane.

In order to reconstruct  $H_d(s)$  from its poles and zeros and the gain factor, we write

$$H_d(s) = \frac{Cs^3}{(s-s_1)(s-s_2)(s-s_3)(s-s_4)}. \quad (5)$$

It is now convenient to pair-wise expand the factors of the denominator into second-order polynomials:

$$H_d(s) = \frac{Cs^3}{(s^2 - s(s_1 + s_2) + s_1s_2)(s^2 - s(s_3 + s_4) + s_3s_4)}. \quad (6)$$

This makes all coefficients real because  $s_2 = s_1^*$  and  $s_4 = s_3^*$ . Since  $s_1 + s_2 = -2\omega_s h_s$ ,  $s_1s_2 = \omega_s^2$ ,  $s_3 + s_4 = -2\omega_g h_g$ , and  $s_3s_4 = \omega_g^2$ , Eq. (6) is in fact the same as Eq. (3). We may of course also reconstruct  $H_d(s)$  from the numerical values of the poles and zeros. Dropping the physical units, we obtain

$$H_d(s) = \frac{383.6s^3}{(s^2 + 0.5027s + 0.1755)(s^2 + 0.1257s + 0.00487)} \quad (7)$$

in agreement with Eq.(4).

Figure 2 shows the corresponding amplitude response of the WWSSN seismograph as a function of frequency. The maximum magnification is 750 near a period of 15 sec. The slopes of the asymptotes are at each frequency determined by the dominant powers of  $s$  in the numerator and denominator of the transfer function. Generally, the low-frequency asymptote has the slope  $m$  (the number of zeros, here = 3) and the high-frequency asymptote has the slope  $m-n$  (where  $n$  is the number of poles, here = 4). What happens in between depends on the position of the poles in the complex  $s$  plane. Generally, a pair of poles  $s_1, s_2$  corresponds to a second-order corner of the amplitude response with  $\omega_0^2 = s_1s_2$  and  $2\omega_0h = -s_1 - s_2$ . A single pole at  $s_0$  is associated with a first-order corner with  $\omega_0 = s_0$ . The poles and zeros however do not indicate whether the respective subsystem is a low-pass, high-pass, or band-pass filter. This does not matter; the corners bend the amplitude response downward in each case. In the WWSSN-LP system, the low-frequency corner at 90 sec corresponding to the pole pair  $s_1, s_2$  reduces the slope of the amplitude response from 3 to 1, and the corner at 15 sec corresponding to the pole pair  $s_3, s_4$  reduces it further from 1 to -1.

**Figure 2** Amplitude response of the WWSSN-LP system with asymptotes (Bode plot).

Looking at the transfer function  $H_s$  in Eq. (1) of the electromagnetic seismometer alone, we see that the low-frequency asymptote has the slope 3 because of the triple zero in the numerator. The pole pair  $s_1, s_2$  corresponds to a second-order corner in the amplitude response at  $\omega_s$  which reduces the slope to 1. The resulting response is shown in a normalized form in the upper right panel of Fig. 5.3 in Chapter 5. As stated [there](#) in section 5.2.6 under point 3, this case of  $n < m$  can only be an approximation in a limited bandwidth. In modern seismograph systems, the upper limit of the bandwidth is usually set by an analog or digital cut-off (anti-alias) filter.

As we have shown in section 5.2.8, the classification of a subsystem as a high-pass, band-pass or low-pass filter may be a matter of definition rather than hardware; it depends on the type of ground motion (displacement, velocity, or acceleration) to which it relates. We also notice that interchanging  $\omega_s, h_s$  with  $\omega_g, h_g$  will change the gain factor  $C$  in the numerator of Eq. (4) from  $E\gamma\omega_g^2$  to  $E\gamma\omega_s^2$  and thus the gain, but will leave the denominator and therefore the shape of the response unchanged. While the transfer function is insensitive to arbitrary factorization, the hardware may be quite sensitive, and certain engineering rules must be observed when a given transfer function is realized in hardware. For example, it would have been difficult to realize a WWSSN seismograph with a 15 sec galvanometer and a 90 sec seismometer; the restoring force of a Lacoste-type suspension cannot be made small enough without becoming unstable.

## 1 Introduction

In contrast to inertial seismometers, which respond to ground acceleration and thus to the second derivative of the displacement with respect to time, strain-seismometers, commonly termed extensometers or strainmeters, respond to the spatial derivatives of the displacement field of the incoming seismic wave or in other words, to a combination of the components of the wave's strain tensor. For this reason, strainmeters are inherently instruments which are sensitive to phenomena with "zero" (i.e., very low) frequency and thus particularly suitable for studying crustal deformations due to solid Earth tides and normal mode oscillations of the Earth. More precisely, linear strainmeters record the changes of the distance between the two points at which the instrument is fixed to the ground, while volumetric strainmeters (dilatometers) record the changes of a volume standard which is imbedded in the ground. An excellent, thorough and comprehensive review of strainmeters with an extensive bibliography was written by Agnew (1986) and is still up to date. Strainmeters were introduced into seismology already by Milne (1888).

## 2 Types of strainmeters

### 2.1 Linear strainmeters

This is the most frequently deployed type of strainmeter. The changes  $dL(t)$  with time  $t$  of a fixed distance  $L$  between two points of the Earth are measured with the help of some length

standard. Only a handful of strainmeters ever measured non-horizontal strains and all these were vertical, by far the majority was measuring horizontal strain. Agnew (1986) distinguishes rod strainmeters, wire strainmeters and laser strainmeters (see Figure 1).

**Figure 1** Schematics of the most frequent strainmeter designs. From top to bottom: rod-, (tensioned) wire- and laser strainmeters. The top two must be equipped with displacement transducers at the right. The bottom sketch indicates the laser, two beam splitters, one corner cube reflector and some sensor (symbol of photodiode) able to detect the change in the interference fringes due to the relative motion of the corner cube reflector on the pedestal to the right.

The length standard should be very stable against all kinds of environmental variables, especially temperature, air pressure and humidity. Because of these requirements, rods are mostly made of quartz, invar or superinvar and wires from invar or carbon fiber. Long rods somehow must be supported without friction, while wires must be tensioned. The length changes are detected by displacement or velocity transducers very similar to the ones used in modern inertial seismometers (see 5.3.7 and 5.3.8). One example of an Invar-rod strainmeter and its installation is described by Fix and Sherwin (1970). A frequently used type of wire strainmeter is described by King and Bilham (1976) and an installation in Widmer et al. (1992). Very short rod strainmeters can be placed in borehole packages, which then must be cemented to the borehole wall. An instrument of this type is described by Gladwin (1984). Laser strainmeters use the wavelength of light as a length standard and an unequal-arm

Michelson interferometer for detection of strains. The interference fringes between the light beams along the long arm (the measuring distance  $L$ ) and a short reference arm are observed with different methods, details of which can be found in the references given by Agnew (1986). It is clear that simple fringe counting necessitates  $L$  to be very large to obtain high enough sensitivity: the wavelength of light is of the order of 500 nm, which is 10 times the amplitude of the Earth tide if  $L$  equals 1 m. Therefore the fringe counting laser strainmeters at Pinion Flat Observatory in California are more than 700 m long (Agnew, 1986; Wyatt et al., 1982, Agnew et al. 1989). Two other laser strainmeters with refined methods to determine the length changes using the fringes are described by Levine and Hall (1972) and by Goult et al. (1974). The smallness of the expected signals with respect to the local noise from changes in the environmental conditions necessitates either installation deep underground in mines or boreholes or possibilities for anchoring the mounts to points deep in the ground (Wyatt et al., 1982). A typical installation depth with hope for success is larger than about 30 m below surface. Shielding the instruments is also mandatory and not as easy as for the much smaller inertial seismometers.

## 2.2 Volumetric strainmeters

Volumetric strainmeters or dilatometers measure the change  $dV(t)$  of a certain volume  $V$ . A borehole instrument of this kind was constructed by Sacks et al. (1971) and widely deployed, especially in Japan. The volume changes are sensed by a liquid-filled tube which is cemented into the borehole. The deformation of the volume causes the liquid to expand or contract bellows, the movement of which is transmitted by a lever arm to displacement transducers. In passing it should be mentioned that water wells drilled into confined aquifers act as sensors for the strain tensor in their vicinity, because applied strains force water in and out of the well, if it is open to the aquifer. Either the level of the water surface or water pressure at a constant depth are measured (e.g. Kümpel, 1992).

## 3 Properties

### 3.1 Sensitivity

A typical strain amplitude  $dL/L$  (no dimension!) of the solid Earth tide is 50 nano ( $50 \cdot 10^{-9}$ ), while Widmer et al. (1992) reported 10 pico ( $10^{-11}$ ) for the fundamental toroidal mode  ${}_0T_2$  of the Earth (see Fig. 2.22) excited by the 1989 Macquarie-Ridge event with a moment magnitude of 8.2. Note that these numbers correspond to one wavelength of (red) light in 10 m and 50 km, respectively. It is obvious that the necessary resolution of the transducer depends critically on the dimension of the strainmeter, i. e. the longer  $L$ , the less resolution is needed to achieve a certain resolution in strain. Agnew (1986) shows a power spectrum of Earth's strain noise (Figure 2) and describes the sources of the noise as follows: above 0.5 Hz body wave energy, machinery and wind-blown vegetation, between 0.05 and 0.5 Hz marine microseisms with high temporal variability and from 1 mHz to 0.05 Hz atmospheric pressure changes deforming the ground (wind turbulence, infrasound) (see 4.3). Below 1 mHz the sources are hard to identify, possibilities being thermoelastic deformations, pore pressure and groundwater changes (Evans and Wyatt, 1984), or air pressure changes. Instrumental effects play an important role at the lowest frequencies (drift) and are not easily ruled out (Zadro and Braitenberg, 1999).

**Figure 2** Power spectral density in (strain squared)/Hz as published by Agnew (1986). This is from the 730 m-NW laser horizontal strainmeter at Pinion Flat, California. This instrument is installed at the surface, but referenced with "optical anchors" to a depth of 30 m (Wyatt et al. 1982). See discussion of noise sources in text.

### 3.2 Frequency response

Lomnitz (1997) discusses the amplification of strainmeters for the case, when the seismic wavelength becomes comparable to the length  $L$ . However, the wavelengths of seismic waves are normally much larger than  $L$ , therefore the dependence of the amplification on the wavelength can be neglected in all but a few exceptional cases. So, basically strainmeters are extremely broadband instruments whose range extends from zero frequency to frequencies of 1 Hz and higher. However, the upper limit of this range depends very critically on the design of the individual instrument since all devices possess parasitic resonances at high frequencies.

### 3.3 Calibration

The method for absolute calibration of a strainmeter depends on the individual instrument. In-situ calibration is highly recommended, that is calibration of the installed device is preferable to calibration calculation from components calibrated in the laboratory. Small displacements of that end of a linear strainmeter, which is fixed to the rock simulates ground motion. Uncertainties arise from the definition of the effective length  $L$ , because basically the piers are part of the instruments and have some extent in length. Greater difficulties arise for instruments which have to be cemented into a borehole (Sacks-Evertson dilatometers, tensor strainmeters), because the strains in the ground are transferred to the actual sensor through the borehole wall, the casing and the cement. In these cases a very rough calibration can be obtained with the help of Earth tide strains, which are theoretically at least known to the order of magnitude. However, very local heterogeneities may complicate this method (King et al., 1976).

### 3.4 Direction sensitivity

**Figure 3** Relative direction sensitivity of linear strainmeters to apparent longitudinal (left) and apparent transversal (right) elastic waves. The strainmeter is indicated by the thick horizontal bar in the center of diagrams. Note that in both cases the strainmeter response is identical for opposite arrival directions.

Dilatometers naturally have isotropic direction sensitivity, the signal does not depend on the direction of arrival of the seismic wave. Figure 3 shows the directional sensitivity patterns of a horizontal strainmeter for longitudinal (left panel) and transversal (right panel) elastic waves. The thick solid bar in the center of each panel indicates the strainmeter. If  $p$  is the angle between the arrival direction of the wave and the direction  $L$ , these functions are described by  $\cos(p) \cdot \cos(p)$  for longitudinal, by  $\sin(2p)$  for transversal waves. This means, that when looking into a certain arrival direction, the sign of the output does not depend on whether the wave comes from the front or from behind. Near the free horizontal surface, vertical strain is proportional to the areal strain (also direction independent), therefore vertical strainmeters provide less information than horizontal strainmeters.

### 3.5 Local arrays of linear strainmeters

If three (or more) horizontal linear strainmeters with different azimuth are deployed at one site, any horizontal component of the strain tensor associated with the incoming wave can be determined from a particular combination of the calibrated signals. Widmer et al. (1992) use this property to demonstrate, that toroidal free oscillation peaks in shear strain spectra do not exist in the areal strain spectrum, a theoretically required result.

### 3.6 Local phase velocity

Assuming a plane elastic wave is recorded by a linear strainmeter and an inertial seismometer at the same station, then one can in principle derive the phase velocity of the wave at this

location. This is due to the fact that the inertial seismometer's output amplitude is proportional to the second derivative of displacement with time (frequency squared), while the strainmeter output is proportional to the spatial derivative (wavenumber).

Depending on the components one can derive equations which relate the frequency-dependent phase velocity with the amplitude spectra of both instruments (Mikumo and Aki, 1964). However, this attractive method has not found many applications, because of local deviations of the deformation field from a simple plane wave (Sacks et al., 1976; King et al., 1976).

### 3.7 Effects of local heterogeneity

It has been already mentioned twice that the interpretation of results from strainmeters is plagued by the distortion of the strainfield of the arriving seismic waves by local heterogeneities. In tidal research this effect is well known to affect amplitudes and phases and in that field the terms: cavity, topographical and geological effects are used. Arrival times and frequencies are not affected, but the local displacement field could differ appreciably from that of a theoretical plane wave even if the approaching wave was plane (see also Wielandt 1993). The scale of these effects is of the order of magnitude of the signal and with purposeful installation one can obtain apparent mechanical amplification up to a factor of 50. Beavan et al. (1979) have shown this with a 1 m-invar wire strainmeter at BFO for earthquakes and tides. Those local effects can be minimized by installing strainmeters far from any local heterogeneities in the long direction, in an area without topography and in/on large homogeneous rock units. However, even with a lot of care these effects cannot be avoided completely. The ground around the instrument and its heterogeneities must be considered a part of the instrument (largely unknown) if amplitudes, phases and waveforms are interpreted and these unknown properties could be a function of time. King et al. (1976) and Sacks et al. (1976) deal with this problem for seismological applications. Beaumont and Berger (1974) suggest using the geological effect on tides for earthquake prediction (see below). For inertial seismometers these effects play a role only at periods much longer than ten seconds, because at higher frequencies the inertial effect (proportional to squared frequency) overwhelms the other contributions to the extent that they are negligible (King et al. 1976). One example, where the locally produced tilts were needed to explain the observations with broadband inertial seismometers was encountered in the near-field of explosions at Stromboli, Italy by Wielandt and Forbriger (1999). Strainseismometers are subject to these effects at all frequencies because they measure in fact differences in the displacement fields. The longer the baseline length  $L$  of a strainmeter, the more one can hope that local effects are averaged out, at least small scale effects. Gombert and Agnew (1996) discuss some results from PFO in this context.

## 4 Some results

The following list is not meant to be comprehensive. It should simply present the spectrum of research possibilities involving strainmeters.

- Strainmeters were successful in recording the Earth's free vibrations and long-period surface waves from the beginning. One famous example is the record of the Isabella, California, quartz-rod strainmeter of the Great Chilean quake 1960 (Ben-Menahem and Singh, 1981, Fig. 5.29). Widmer et al. (1992) and Zürn et al. (2000) show shear

strain spectra from 10 m Invar wire strainmeters at BFO where the fundamental toroidal mode of the Earth,  ${}_0T_2$  with a period of 44 minutes, stands clearly above the noise floor for the Macquarie 1989 and Balleny Island 1998 events, respectively. The disastrous N-Sumatra–Andaman Islands earthquake on December 26, 2004, excited the seismic free oscillations of the Earth to the largest amplitudes since 1964. Several strainmeters were recording those with unprecedented quality. Park et al. (2008) analyzed spectra from the records of two orthogonal laser extensometers in the Gran Sasso observatory, Italy with very clear observation of the lowest degree fundamental toroidal modes. The strainmeter array at BFO also provided very high quality records. Fig. 4 shows spectra of areal and shear strains computed from the records (Widmer et al. 1992) of three linear strainmeters with the fundamental spheroidal and toroidal modes. The “breathing mode”  ${}_0S_0$  stands out clearly in the spectrum of areal strain, its initial amplitude was estimated to  $8.8 \times 10^{-12}$ .

**Figure 4** Spectra of areal (top) and shear (bottom) strains calculated from the records of the three linear strainmeters at BFO. Toroidal modes are missing in the areal strain and enhanced with respect to spheroidal modes in the shear strains. Many of the multiplets show splitting due to symmetry breaking by rotation and ellipticity. The “breathing mode”  ${}_0S_0$  is missing in the shear strain, its frequency is indicated by the dotted line. A barometer correction was applied to the linear strain data.

- Coseismic steps consistent with source theory were repeatedly observed with the laser strainmeters at PFO for earthquakes in California (Wyatt, 1988; Agnew and Wyatt, 1989).
- Very clear postseismic strain signals lasting many days were recorded at PFO, California by the laser strainmeters, the borehole tensor strainmeter (Gladwin, 1984) and several tiltmeters (Wyatt et al. 1994) for the 1992 Landers earthquake sequence. The authors conclude that possibly different processes contribute to the observed signals and discuss those.
- Linde et al. (1993) were able to derive a detailed picture of the mechanism of an eruption of Hekla volcano, Iceland from the records of several Sacks-Evertson borehole dilatometers installed between 14 and 45 km away from the summit.
- Slow and silent earthquakes have repeatedly been reported from records by borehole dilatometers in California and Japan (e. g. Linde et al. 1996).
- Earth tides are continuously probing the Earth with periods of 12 and 24 hours. They can be used to study the response of the rocks. Agnew (1981) tried to find out about nonlinear behaviour of the rocks using data from the laser strainmeters at PFO. He concludes, that in the absence of evidence for nonlinearity from the tides, seismologists are justified in treating the Earth as a linear system. This kind of study is limited by the strain effects of nonlinear ocean tides.
- Beaumont and Berger (1974) suggested from experiments with Finite-Element models, that the earthquake preparation process should modify rock properties near the fault (i.e., by dilatancy) and thus the amplitudes of the tidal strains observed near the fault. Several groups made attempts to make such observations with no success up to date: Linde et al. (1992) looked at borehole dilatometer and tensor strainmeter records in the vicinity of the Loma Prieta, California, quake in 1992 and Omura et al. (2001) investigated super-invar bar-strainmeter data around the 1995 Kobe earthquake from a mine at a distance of 25 km from the epicenter (see also Westerhaus and Zschau, 2001, for a short summary of other attempts) . Latynina and Rizaeva (1976) report tidal strain amplitude variations observed with quartz rod strainmeters before an earthquake, but are not certain about the significance of this result.
- Secular crustal deformation rates have been always a major observation goal for strainmeters. Basically they are able to see this signal, but because of the high and non-stationary noise at ultra-low frequencies, the interpretation in this spectral band is extremely difficult. The work with the very long laser strainmeters at Pinion Flat (PFO), in combination with other instruments and methods, is the most careful one (see articles by Agnew, Wyatt and colleagues) ever performed in this direction. PFO is located between the San Andreas and San Jacinto faults in Southern California and only 10 to 15 km away from both.

## 5 Strain- vs. inertial seismometers

In practice inertial seismometers by far outnumber strainmeters. It is also a fact that experimental seismological research is based mainly on the records from inertial seismometers with very few contributions from the few strainmeters. More than 100 borehole tensor strainmeters (type: Gladwin, 1984) and long-baseline laser strainmeters will be installed (starting 2004) at the Plate Boundary Observatory in the Western United States in order to detect strain signals close to the active faults. Although this presents a large boost in the total number of strainmeters it will not yet change the general imbalance in the use of strainmeters as compared to inertial seismometers.

There are several reasons for this imbalance:

- Inertial seismometers, short-period and broadband, are commercially available, while highly sensitive strainmeters are not. The costs to produce a competitive laser strainmeter are very high, but a Cambridge type wire strainmeter can be produced very cheaply, compared to the cost of a modern broadband seismometer.
- Short-period and most broadband seismometers are very easy to set up. STS-1 seismometers need more care if highest quality is requested. Strainseismometers require much more work for their installation. Borehole seismometer and borehole strainmeter installation probably is comparable.
- By far the most seismological routine work, especially at the regional scale with local networks, is performed analyzing body waves with periods of a few seconds to frequencies of several tens of Hz. At these frequencies most strainmeters, due to their relatively large dimension, suffer from parasitic resonances of some kind depending on the individual design. Possible exceptions are the Sacks-Evertson dilatometer and the borehole tensor strainmeters because they are more compact.
- Strainmeters, in contrast to short-period seismometers, are extremely noisy if installed near the surface of the Earth due to environmental variations of temperature and air pressure and their effects on the instrument itself and the ground around it. Therefore high quality can only be obtained in boreholes, mines and tunnels or by anchoring them to points at depth. This leads to added installation costs, especially if boreholes have to be drilled for the installation. Basically the cost of the borehole has to be added to the cost of the instrument.

It is noted here that the users of global digital broadband data know the differences in quality between vertical and horizontal components as a function of the depth of installation. At long periods the horizontals are very sensitive to tilts (see 5.3.3). Both tilt and strain are local spatial derivatives of the displacement field and show similar local effects in terms of noise and distortions. Therefore the fairest comparison for strainmeters would be to the long-period horizontal inertial seismometers.

For a given input wave amplitude, the amplitude of the output signal is proportional to  $1/\lambda = f/c$  for a strainmeter and  $\sim f^2$  for an inertial seismometer (with  $\lambda$  - wavelength,  $f$  - frequency,  $c$  - phase velocity). Accordingly, when considering waves with equal  $c$ , strainmeters have more and more advantage the lower the frequency gets (for both types of sensors the noise power (see Figure 2) rises strongly with decreasing frequency). Most of the research cited above belongs to "zero-frequency seismology". Low-frequency research work makes sense especially in the near-fields of earthquake faults and active volcanoes (creep events, slow and

silent earthquakes, pre-, co- and postseismic strain transients, de- and inflation periods, etc.) . However, it is prudent not to rely on a single instrument because noise at very long periods is non-stationary and any changes in the coupling of the instrument to the ground or in the materials of the instrument itself will appear as a signal.

## 1 The BODE diagram

*True ground motion* is of major interest in seismology. On the other hand any measuring device will alter the incoming signal as well as any amplifier and any output device. Working in the frequency domain, the quotient of input signal and output signal is called the *response*. This response is complex, and to get a more meaningful result it can be split into two terms: amplitude response and phase response (see 5.2.3). Amplitude response means the output amplitude divided by the input amplitude at a given frequency. Phase response is the difference between output phase and input phase, or the phase shift. A graphical expression of this splitting is known as the BODE-diagram. One part shows the logarithm of amplitude  $A$  versus the logarithm of frequency  $f$  (or angular frequency  $\omega$ , or period  $T$ , see Figure 1a). The other part depicts the (linear) phase  $\phi$  versus the logarithm of frequency  $f$  (or  $\omega = 2\pi f$ , or  $T = 1/f$ , see Figure 1b). For  $A$  the terms *amplification* or *magnification* are also used.

### 1.1 The signal chain

The signal passes a chain of devices. Any single element of this chain can be described by its response. It is useful to split any response into elements of first or second order. At the end the overall amplitude response of the complete chain can be constructed by multiplying all single amplitude responses, and the overall phase response by adding all single phase shifts.

### 1.2 First and second order elements

For the amplitude response the double logarithmic scale of the amplitude diagram facilitates an easy and fast construction. Any element can be approximated by two straight lines. One horizontal line leads to the element corner frequency, and one line drops from that point with a slope depending on the order of the element.

A first order element is completely described by its amplification  $A$  and corner frequency  $f_c$ . The slope beyond  $f_c$  is one decade in amplitude per decade in frequency. The real amplitude value at  $f_c$  is dropped to 0.707 of the maximum amplitude (see Figure 2, full line). However, for our fast construction, we consider only a linear approximation to it (dash-dot lines).

A second order element exhibits a slope of two decades in amplitude per decade in frequency. Additionally it needs another parameter called damping  $D$ , describing the amplitude behaviour at frequencies near  $f_c$  (compare Figure 3).

## 2 The seismological signal chain

The seismological signal passes the chain

- mechanical receiver
- transducer
- preamplifier
- filter
- recording unit (to be recognized separately)

**Note!** Below we discuss in sections 2.1 and 2.2 amplitude responses related to ground displacement. Therefore, the ordinate axis of the BODE-diagram (amplitude  $A$ ) for the mechanical receiver has no unit (or the unit  $[m/m]$ ), and for the transducer the unit is  $[V/m]$ . Changes to other types of movement, being proportional to ground velocity or to ground acceleration, will be described in section 3.

### 2.1 The mechanical receiver

The mechanical receiver is a second order system. It describes the relative movement of the pendulum (i.e., a seismic mass attached to a frame by a spring) with respect to the frame. Damping  $D$  is set mostly to 0.707. Only at this damping value is the amplitude value at  $f_c$  also 0.707 (Figure 3, full curve). For higher values of damping one obtains a more flat curve (dashed). For lower values of  $D$  the dash-dot curve strongly exceeds the amplification level at  $f_c$ , indicating low-damped resonance oscillations of the pendulum, which can be stimulated by any signal.

The amplification of the mechanical receiver is  $A = 1$ . This means that for frequencies  $f > f_c$  the amplitude of the pendulum movement with respect to the frame is similar to the ground amplitude. For the phase shift see Figure 7b (HIGH Pass 2).

### 2.2 The transducer

The transducer transforms the relative movement of the pendulum into an electrical signal, i.e., in a voltage. The transducer constant  $G$  gives the value of the output voltage  $U$  depending on the relative pendulum movement  $z$ . There are three main types of transducers, distinguished by their proportionality to ground motion and its derivatives:

- |                |                    |               |                                             |
|----------------|--------------------|---------------|---------------------------------------------|
| - Displacement | $U \sim z$         | $G_d[V/m]$    | (capacitance or inductance bridges)         |
| - Velocity     | $U \sim dz/dt$     | $G_v[Vs/m]$   | (magnet-coil systems)                       |
| - Acceleration | $U \sim d^2z/dt^2$ | $G_a[Vs^2/m]$ | (piezo-electric systems, $U \sim F = m a$ ) |

The above proportionality of the transducer voltage to ground motion (i.e., to displacement, velocity or acceleration, respectively) is, of course, only given for frequencies  $f > f_c$ , i.e., for the horizontal part of the mechanical receiver response (see Figure 3).

All transducer amplitude responses can be drawn as straight lines over the full considered frequency range (Figure 4). They differ only in their slope.

The phase responses have a constant phase shift over the whole frequency range with values of  $0^\circ$  (displacement),  $90^\circ$  (velocity), or  $180^\circ$  (acceleration).

### 2.3 The preamplifier

The preamplifier is a first order LOW Pass. Its corner frequency is beyond the signal range of seismology - up to several 10 kHz. Thus, only the amplification is of interest (Figure 5). The response is a horizontal line drawn at the amplification level  $A$ .

The phase shift is  $\phi = 0^\circ$ , but one should keep in mind that, if using the inverted input, the phase shift will be  $\phi = -180^\circ$  over the whole frequency range.

### 2.4 First and second order LOW Passes

LOW Passes have constant amplifications  $A$  for frequencies lower than their corner frequencies  $f_c$ . For frequencies higher than  $f_c$  the amplification drops with a slope depending on the order of the filter (Figure 6a). LOW Passes cut the high frequencies, therefore, also the term High Cut is used. The phase shift for  $f < f_c$  is about  $0^\circ$  and for  $f > f_c$  it turns to  $-90^\circ$  (first order, LP1) or  $-180^\circ$  (second order, LP2; see Figure 6b), passing half of the phase shift exactly at  $f_c$ .

Of course, the given amplitude and phase values are approximations. In reality we would obtain  $\phi = 0^\circ$  only if inserting a frequency of 0 Hz, and  $\phi = -90^\circ$  ( $-180^\circ$ ) for infinite frequency values. However, the accuracy is sufficient for our fast construction.

### 2.5 First and second order HIGH Passes

HIGH Passes have constant amplifications  $A$  for all frequencies higher than their corner frequency  $f_c$ . For frequencies lower than  $f_c$  the amplification drops with a slope depending on their order (Figure 7a). They cut the low frequencies, so one can also find the term Low Cut.

The phase shift for  $f > f_c$  is about  $0^\circ$ , and for  $f < f_c$  it turns to  $+90^\circ$  (first order, HP1) or  $+180^\circ$  (second order, HP2; see Figure 7b), passing half of the phase shift exactly at  $f_c$ .

Comparable to the description of LOW Passes the given amplitude and phase values are approximations.

### 2.6 Second order BAND Pass

The second order BAND Pass (BP2) can be explained as a combination of a first order LOW Pass and a first order HIGH Pass. It suppresses all frequencies, except  $f_c$ , with a slope of one decade in amplitude per decade in frequency (Figure 8a). The peak at  $f_c$  can be turned into a horizontal line (symmetrical to  $f_c$ ) by increasing the damping to values  $D > 1$ . Thus it is possible to construct a BAND Pass by combining a HIGH Pass with a LOW Pass.

The phase shift for  $f < f_c$  is about  $+90^\circ$ , and for  $f > f_c$  it turns to  $-90^\circ$  (see Figure 8b), passing half of the phase shift at  $f_c$ .

### 3 The overall response

The construction of the overall response should be divided into two steps:

- from mechanical receiver to the final filter stage; and
- adding the recorder response.

The first result, the electrical output, is useful for fitting the signal to the recorder input. It has to be fixed, meaning that changes in magnification (or signal resolution) should be done by setting up the recorder only.

#### 3.1 From the mechanical receiver to the final filter

As defined in section 2, the amplitude response is constructed related to ground displacement. Multiplying all the units of our signal chain, we get the unit  $[V/m]$  for the ordinate axis. All elements, including mechanical receiver, transducer, and filter stages can be implemented in the same sheet with a double logarithmic grid, each element with its magnification and its corner frequency. Then the resulting amplitude response has to be constructed point by point at certain frequencies. This can be done either by multiplying the amplitudes of all elements at these frequencies, which is the more secure method, or, alternatively, by adding the distances (e.g., in millimetres) of all element amplitudes to the amplitude level line  $A = 1$ , with positive distances if above this line and negative ones if below. This method is faster. A linear addition is, in this logarithmic scale, a multiplication of the amplitude values. The final amplitude response curve can be drawn on the same sheet, together with the single elements.

#### 3.2 Adding the recorder

In reality, at the end of our signal chain we will find a commercially available recorder, transforming the obtained voltage back into movement (drum recorder) or into computable digital values (Analogue-to-Digital Converter = ADC). Its main parameter is the input sensitivity  $H$ . In the case of a drum recorder,  $H$  is the pen deflection per Volt (in units  $[m/V]$ ). For an ADC,  $H$  is the digital count per Volt (in units  $[digit/V]$ ).

Thus the overall amplitude response needs a separate BODE-diagram for each recorder type. Multiplying the units we obtain the units  $[m/m]$  for the drum recorder, and  $[digit/m]$  for the ADC. You will also find derivatives of this unit, like  $[digit/nm]$  or  $[counts/nm]$ .

#### 3.3 Introducing ground velocity and ground acceleration

If the amplitude response curve has to be constructed related to ground velocity (or ground acceleration), it is sufficient to redraw either the response of the mechanical receiver or the transducer. The simpler method is to change the transducer response. Each slope will change by one order if going from displacement to velocity, or from velocity to acceleration. The unit of the ordinate changes from  $[V/m]$  (displacement) via  $[Vs/m]$  (velocity) to  $[Vs^2/m]$  (acceleration). These units will also be the units of the amplitude response from the mechanical receiver to the final filter stage. Beyond this the construction of the overall amplitude response is similar to section 3.1. The units of the recorder amplitude response will alter to  $[m\cdot s/m]$  (velocity) or  $[m\cdot s^2/m]$  (acceleration) for the drum recorder. For the ADC we obtain  $[digit\cdot s/m]$  (velocity) or  $[digit\cdot s^2/m]$  (acceleration).

# 1 Introduction

Rotational seismology is an emerging study of all aspects of rotational motions induced by earthquakes, explosions, and ambient vibrations. The subject is of interest to several disciplines, including seismology, earthquake engineering, geodesy, and earth-based detection of Einstein's gravitation waves. In this chapter, we will present basic elements of measuring rotational ground motions in seismological practice and an overview of recent observations. Because there are terms in this Chapter that may not be familiar to the readers, readers may consult either the amended **Glossary** of this manual, or for an even more detailed glossary on rotational seismology Lee (2009).

Likely rotational effects of earthquake waves together with rotations caused by soil-structure interaction have been observed for centuries (e.g., rotated chimneys, monuments, and tombstones relative to their supports). A summary of historical examples of observations on earthquake rotational effects is provided by Kozák (2009), including reproduction of the relevant sections from Mallet (1862) and Reid (1910). Figure 1 shows the rotation of the monument to George Inglis (erected in 1850 at Chatak, India) as observed by Oldham (1899) after the 1897 Great Shillong earthquake.

**Figure 1** Rotation of the monument to George Inglis (erected in 1850 at Chatak, India) as observed by Oldham (1899) after the 1897 Great Shillong earthquake. This monument had the form of an obelisk rising about 20 m high from a base 4 m on each side. During the earthquake, the topmost 2 m section was broken off and fell to the south and the next 3 m section was thrown to the east. The remnant is about 6.5 m in height and is rotated about 15° relative to the base. Such rotations can be due to strictly translational accelerations and don't necessarily require rotational ground motion (see text).

A few early authors proposed rotational waves or at least some “vortical” motions. Many different terms were used for the rotational motion components at this early development stage. For example, “rocking” is rotation around a horizontal axis, sometimes also referred to as “tilt”. Mallet (1862) proposed that rotations of a body on the Earth's surface are due to a sequence of different seismic phases emerging at different angles. Computational modelling by Hinzen (2010) also demonstrates such effects.

Reid (1910) studied this phenomenon, which was observed in the 1906 San Francisco earthquake, and pointed out that the observed rotations are too large to be produced by waves of linear elastic distortion. Such waves “*produce very small rotations, whose maximum amount, ... is given by the expression  $2\pi A = \lambda$ , where  $A$  is the amplitude and  $\lambda$  the wavelength;*

with a wave as short as 10,000 feet (3 km) and an amplitude as large as 0.2 of a foot (6 cm), the maximum rotation would only be about 0.25 of a minute of arc [ $7.3 \mu\text{rad}$ ], a quantity far too small to be noticeable.” (Reid, 1910, p. 44). A modern analysis of such rotational effects is presented in Todorovska and Trifunac (1990).

Observational seismology is based mainly on measuring *translational* motions because of a widespread belief that *rotational* motions are insignificant. For example, Richter (1958, footnote on p. 213) states that “*Theory indicates, and observation confirms, that such rotations are negligible.*” Richter provided no references (but perhaps after Reid, 1910, p. 44), and there were no instruments at that time sensitive enough to either confirm or refute this claim. Recent advances in rotational seismology became possible because sensitive rotational sensors have been developed in aeronautical and astronomical instrumentation.

## 2 Early attempts to study rotational motions

Ferrari (2006) summarized two models of an electrical seismograph with sliding smoked paper, developed by P. Filippo Cecchi in 1876 to record three-component *translational* motions and also the *torsional* movements from earthquakes. Although these instruments operated for several years, no rotational motion could be recorded because of low transducer sensitivity. Pioneers in several countries attempted to measure rotational motions induced by earthquakes. Nearly a century ago, Galitzin (1912) suggested using two identical pendulums installed on different sides of the same axis of rotation for separate measurement of rotational and translational motion. This was later implemented, for example, by Kharin and Simonov (1969) in an instrument designed to record strong ground motion. Using an azimuthal array of seismographs, Droste and Teisseyre (1976) derived rotational seismograms for rock bursts in a nearby mine. Inspired by Walter Munk, Farrell (1969) constructed a gyroscopic seismometer, and obtained a static displacement of  $<1$  cm and a tilt of  $<0.5 \mu\text{rad}$  at La Jolla, California, during the Borrego Mountain earthquake of 09 April 1968 (magnitude 6.5) at an epicentral distance of 115 km.

Early efforts also included studies of explosions. For example, Graizer (1991) recorded tilts and translational motions in the near-field of two nuclear explosions using seismological observatory sensors to measure point rotations directly. Nigbor (1994) measured rotational and translational point ground motions directly with a commercial rotational micro-electro-mechanical system (MEMS) sensor and found significant near-field rotational motions ( $660 \mu\text{rad}$  at 1 km distance) from a one-kiloton explosion.

Rotations and strains of the ground and in the response of structures have been deduced indirectly from accelerometer arrays using methods valid for seismic waves having wavelengths that are long compared to the distances between sensors (e.g., Trifunac 1979; 1982; Oliveira and Bolt, 1989; Spudich et al., 1995; Bodin et al., 1997; Huang, 2003; Suryanto et al., 2006; Wassermann et al., 2009). The rotational components of ground motion have also been estimated theoretically, using kinematic source models (Bouchon and Aki, 1982; Wang et al., 2009) and linear elastodynamic theory of wave propagation in elastic solids (Lee and Trifunac, 1985, 1987). Recently, Graizer and Kalkan (2010) presented a history of strong motion seismology and rotations, outlining also future directions.

### 3 Techniques for measuring rotational motions

The general motion of the particles or a small volume in a solid body can be divided into three parts: translation (along the X-, Y-, and Z-axes), rotation (about the X-, Y-, and Z-axes), and strain (six components). Figure 2(a) shows the axes in a Cartesian coordinate system for *translational velocity* measured by the usual sort of seismometers used in seismology, and Figure 2(b) shows the corresponding axes of *rotation rate* measured by rotational sensors (Evans and the International Working Group on Rotational Seismology, 2009). These are “body attached” coordinates, those that a seismic instrument would measure at a given instant as the sensors move and rotate through space. Converting an extended record of these body-fixed motions to recover motions in an Earth-fixed, quasi-inertial coordinate system has been performed for decades in “strapped down” inertial navigation systems such as those attached to a moving airplane. Lin et al. (2010) introduce these equations into seismology and earthquake engineering for recovering inertial-frame ground and structure motions.

**Figure 2** Coordinate system for translational velocity (adopted from Figure 1 of Evans and the International Working Group on Rotational Seismology, 2009). (a) Coordinate system for translational velocity. (b) Coordinate system for body-fixed or instantaneous rotational rate. This is the preferred nomenclature and sign conventions for observed translational and rotational motions in seismology and earthquake engineering. X and Y axes point into the page and are normally in the horizontal plane. Note the positions of rotation gyres with respect to the axes (the line in front breaks the line behind). Axes point in the positive directions of both the translational vectors and rotation vectors.

Annotations  $v$  and  $\dot{\omega}$  are translational velocity (m/s) and rotation rate (rad/s); the subscripts x, y, and z refer to the X, Y, and Z components.

#### 3.1 Theoretical basis

Rotational motion in seismology is usually formulated in the framework of linear elasticity theory with the assumption of *infinitesimal deformation* (Cochard et al., 2006). In a linear elastic medium the displacement  $\mathbf{u}$  of a point  $\mathbf{x}$  is related to a neighboring point  $\mathbf{x} + \delta\mathbf{x}$  by

$$\mathbf{u}(\mathbf{x} + \delta\mathbf{x}) = \mathbf{u}(\mathbf{x}) + \boldsymbol{\varepsilon} \delta\mathbf{x} + \boldsymbol{\omega} \times \delta\mathbf{x} \quad (1)$$

where  $\boldsymbol{\varepsilon}$  is the strain tensor and

$$\boldsymbol{\omega} = \frac{1}{2} \nabla \times \mathbf{u}(\mathbf{x}) \quad (2)$$

is a pseudo-vector representing the infinitesimal angle of rigid rotation generated by the disturbance. The three components of rotation about the X-axis, Y-axis and Z-axis are given by the following equations for such infinitesimal motions:

$$\begin{aligned} \omega_x &= \frac{1}{2} (\partial u_z / \partial y - \partial u_y / \partial z), \\ \omega_y &= \frac{1}{2} (\partial u_x / \partial z - \partial u_z / \partial x), \\ \omega_z &= \frac{1}{2} (\partial u_y / \partial x - \partial u_x / \partial y) \end{aligned} \quad (3)$$

Therefore, rigid rotations can be observed: (i) indirectly, by an array of translational seismometers for “cord” rotations associated with long wave lengths by assuming that contamination of translational signals by rotational motions is small, and that the linear elasticity theory is valid (e.g., Spudich and Fletcher, 2008), or (ii) directly, by rotational sensors for “point” body-fixed rotations (e.g., Lee et al., 2009b, and Lin et al., 2010).

Although classical elasticity theory works well for earthquakes in the *far* field recorded by vaulted seismographs, this linear theory may not be applicable in the *near* field. Theoretical work suggests that in shallow granular, cracked or biologically-disturbed, often dry continua (e.g., soil or weathered rock at or near Earth’s surface), asymmetries of the stress and strain fields can create rotations separate from and larger than those predicted by classical elastodynamic theory (e.g., Teisseyre et al., 2006; 2008; Teisseyre, 2010). If so, these exaggerated rotations join previously known translational “site effects” for strong-motion stations. Further, unlike the traditional fault-slip model (Aki and Richards, 2002, p. 38-59) assuming a fault zone of *zero thickness*, Knopoff and Chen (2009) consider the case of faulting that takes place on a fault zone of *finite thickness*. They show that there is an additional single-couple term in the body-force equivalence and additional terms in the far-field displacement. They also show that the single-couple equivalent does not violate the principles of Newtonian mechanics because the torque imbalance in the single-couple is counterbalanced by rotations within the fault zone, with torque waves being radiated.

### 3.2 Measuring considerations

Most seismological instruments used in measuring translational ground motion are pendulum seismometers and accelerometers, and a tutorial on measuring rotations using multi-pendulum systems is given in Graizer (2009). It is important to note that pendulums are sensitive to translational motion and rotations. Horizontal pendulums are sensitive to the acceleration of linear motion, tilt, angular acceleration, and cross-axis excitations; and vertical pendulums are sensitive to the acceleration of linear motion, angular acceleration, and cross-axis excitations but not to tilt. Graizer (2005, 2010) provided complete equations of pendulum sensors used in seismology and their approximation for strong-motion seismology and also presented a method (Graizer, 2006) to extract residual tilt from uncorrected strong-motion accelerograms.

Measuring rotational ground motions is closely related to the traditional seismological observations of translational ground motions, and measurements of tilts and strains. However, it is beyond the scope of this Chapter to discuss tiltmeters and strainmeters. For these instruments, interested readers may consult, e.g., Agnew (1986), Segall (2010) and IS 5.1 by Zürn (2002) and in this NMSOP2.

## 4 Measuring rotational motions in practice

In the past decade, rotational motions from small local earthquakes to large teleseisms have been recorded successfully by sensitive rotational sensors in several countries (e.g., Takeo, 1998; McLeod et al., 1998; Igel et al., 2005, 2007; Suryanto et al., 2006; Cochard et al., 2006). In particular, the application of Sagnac interferometry in large ring-laser gyros provided greatly improved sensitivity to rotations at teleseismic distances and showed that the measured rotations are a good match to those estimated from linear elastic wave theory. Combined with translations, such rotational motions provide additional observations that lead to new approaches to the seismic inverse problem (Bernauer et al., 2009; Fichtner and Igel, 2009). Recently Igel et al. (2010) reported the first observations of Earth's free oscillations using ring laser recordings, and opened up potential applications of rotational seismology at long periods.

In contrast, strong-motion observations near the source in both Japan and Taiwan show that the amplitudes of these rotations can be one to two orders of magnitude greater than that expected from linear elasticity theory (e.g., Takeo, 1998; Lee et al., 2009b).

### 4.1 Ring laser gyros

An unexpected advance in studying rotational ground motions came from a different field of geophysics. Recent developments of highly sensitive ring laser gyroscopes to monitor the Earth's rotation also yield valuable data on rotational motions from large teleseismic events (Schreiber, 2009). The most important property that makes such rotation sensors useful for seismology is its very low noise floor and high sensitivity to rotational motions and its insensitivity to translational and cross-rotational motions. Very recently, the 3 September 2010 Canterbury, New Zealand earthquake ( $M_w$  7.0) occurred near the Canterbury ring-laser station, which recorded many of the aftershocks (Schreiber, personal communication, 2010).

The rotation rates expected and observed in seismology range from the order of  $10^{-1}$  rad/s (e.g., Nigbor, 1994; Trifunac 2009) for near seismic sources down to order  $10^{-11}$  rad/s for large earthquakes at teleseismic distances (e.g., Igel et al., 2005, 2007). This range spans at least 10 orders of magnitude (200 dB), much as do translational motions, and it is unlikely that one instrument or one instrumental technology will be capable of providing accurate measurements over such a large range of amplitudes. Ring laser technology is currently the most promising approach to recording the small rotational motions induced by teleseisms, but to reach the sensitivities needed for seismic measurements large sizes (several square meters) are necessary and therefore the primary drawback of this technology is its very high cost.

#### 4.1.1 Ring laser technology

Ring lasers detect the Sagnac beat frequency of two counter-propagating laser beams (Stedman, 1997; and Figure 3(c)), and Schreiber (2010) reviews the recent progress in ring laser technology. These active interferometers generally form triangular or square closed loops several meters across. The cavity is accurately evacuated and filled with a mixture of helium and neon for the laser, and the instrument is vacuum tight. If this instrument is rotating on a platform with respect to inertial space, the effective cavity length between the co-rotating and counter-rotating laser cavities differ and one observes frequency splitting

resulting in a beat frequency. This beat frequency  $\delta f$  is directly proportional to the rotation rate  $\Omega$  around the surface normal  $\mathbf{n}$  of the ring laser system, as given by the Sagnac equation:

$$\delta f = \frac{4A}{\lambda P} \mathbf{n} \cdot \Omega, \quad (4)$$

where  $P$  is the perimeter of the instrument,  $A$  its area, and  $\lambda$  the laser wavelength. This equation has three contributions that influence the beat frequency  $\delta f$ : (a) variations in the scale factor ( $4A/\lambda P$ ) have to be avoided by means of a servo system which keep the perimeter of the ring constant; (b) changes in orientation  $\mathbf{n}$  (tilting relative to Earth's rotation axis) enter the beat frequency *via* the inner product; and (c) variations in  $\Omega$  (e.g., changes in Earth's rotation rate and seismically induced rotations). The dominant contribution to  $\delta f$  is  $\Omega$ . Note that translations do not contribute to the Sagnac frequency unless they affect  $P$  or  $A$  in some indirect manner. Next generation ring-laser gyro should have 3 axes attached to the same monument.

Ring lasers are sensitive to rotations only, assuming stable ring geometry and lasing. However, for co-seismic observations at the Earth's surface the horizontal components of rotation (i.e., tilts) will contribute to the vertical component of rotation rate (via  $\mathbf{n}$  in Equation (4)). As shown by Pham et al. (2009), the tilt-coupling effect is several orders of magnitude below the level of the earthquake-induced rotational signal unless one is very close to the source (where sensitive ring lasers would not be the appropriate technology; see next Section).

At present, there are ring laser gyros capable of measuring rotations induced by small local earthquakes or distant large teleseisms at four sites: 1.) Cashmere cavern, Christchurch, New Zealand (McLeod et al., 1998), 2.) Wettzell, Germany (Schreiber et al., 2005), 3.) Conway, Arkansas (Dunn et al, 2009), and 4.) Piñon Flat, California (Schreiber et al., 2009a). The ring laser gyros in these 4 sites all measure the vertical component of rotation rate (rotation about the vertical axis). However, measuring the horizontal components (rotations about horizontal axes) using ring laser technology is under development, e.g., VIRGO, Pisa, Italy (Di Virgilio, 2010).

#### 4.1.2 G Ring laser and recording teleseisms

Since 2001, the “G Ring” laser (capable of measuring rotation rate of about  $10^{-12}$  rad/s) has been operating at the primary geodetic station (Fundamentalstation) at Wettzell, in Bavaria (<http://www.fs.wettzell.de/>, last accessed 21 January 2011), along with many other geodetic instruments. A cross-sectional view of the site of the G Ring Laser is shown in Figure 3(a). The instrument is resting on a polished table consisting of a Zerodur™ disk (originally planned for a telescope) (Figure 3(b)) embedded in a 90-ton concrete monument. As shown in Figure 3(a), the monument is attached to a massive 2.7-m diameter concrete pillar and this is founded on crystalline bedrock 10 m below. A system of concrete rings and isolation material shields the monument and pillar from adjacent weathered-rock to eliminate its deformation and heat-flow contributions. The G Ring Laser is protected against external influences by a subsurface installation with passive thermal stability provided by a 2-m layer alternating between Styrofoam and wet clay, this beneath a 4-m soil mound. A lateral entrance tunnel with five isolating doors and a separate control room minimize thermal perturbations during maintenance. In addition the complete Zerodur™ table is covered by a

pressure tight casing which is lowered after maintenance - this results in a huge improvement of the signal/noise ratio.

After two years of thermal adaptation, the average temperature reached 12.2 °C with seasonal variations of less than 0.6 °C. Figure 3(c) shows the schematic drawing of instrument, and Figure 3(d) is a photo of the G Ring laser with its designer, Ulli Schreiber. The G Ring laser is large and sit on top of an impressive monument to reach extremely high sensitivity to study variations of the Earth's rotation. For seismological practice, a ring laser on top of a lighter monument will be adequate, as is the ring laser at Piñon Flat, California.

**Figure 3** G Ring laser gyro at the Wettzell Superstation, Germany. (a) Cross-sectional view of the instrument site. (b) Instrument resting on a granite table. (c) Schematic drawing. (d) Photo of G Ring laser gyro with its designer, Ulli Schreiber.

Figure 4 is a comparison of direct point measurements of ground rotations around a vertical axis (red lines) to transverse accelerations (black lines, converted to rotation rate for each time window) for the M8.1 Tokachi-oki earthquake, 25 September 2003 (Igel et al., 2005). Figure 4(a) is a schematic view of the great-circle-path through the epicenter in Hokkaido, Japan, and the observatory in Wettzell, Germany. Figure 4(b–e) show the superposition of the rotation

rate derived from transverse translations (black) and measured directly (red) for various time windows: (b) the complete signal, (c) the latter part of the surface wave train, (d) the direct S-wave arrival, and (e) for the initial part of the surface wave train. These results confirm the expectation from linear elasticity that the waveforms of transverse acceleration and rotation rate (around the vertical axis) should be identical assuming plane harmonic waves. Information on subsurface structure is contained in the ratio between the corresponding motion amplitudes.

**Figure 4** Comparison of direct measurements of ground rotational motions around a vertical axis (red lines) with transverse accelerations (black lines, converted to rotation rate for each time window) for the M8.1 Tokachi-oki earthquake, 25 September 2003 (after Igel et al., 2005).

## 4.2 Strong-motion inertial angular sensors

In aerospace, automotive, and mechanical engineering, smaller rotational-motion sensors are common and generically known as gyroscopic or inertial angular sensors. Nigbor (1994) used a MEMS-based Coriolis rotation-rate sensor to measure the rotational components of strong ground motions close to a large chemical explosion, and unsuccessfully attempted to resolve rotational earthquake motions in southern California for a decade. Similar sensors were used

by Takeo (1998) to measure rotational motions from an earthquake swarm ~3 km away. However, such sensors do not have the sensitivity to record rotations from small local earthquakes (magnitude  $\approx 4$ ) at distances of tens of kilometers.

#### 4.2.1 The eentec™ Model R-1™ rotational seismometer

The eentec™ model R-1™ rotational seismometer is the first modestly-priced (about US\$5,000 each) three-component sensor capable of recording small earthquakes at distances up to several tens of kilometers. It uses electrochemical technology in which the motion of an electrolytic fluid inside a torus is sensed electronically, yielding a voltage signal proportional to rotational velocity. (For more information on this pioneering transducer principle see Vol. 1, Chapter 5, subsection 5.3.10). Nigbor et al. (2009) carried out extensive tests of commercial rotational sensors and concluded that the R-1 sensor generally meets the specifications given by the manufacturer but that clip level and frequency response vary from those specifications and between individual channels enough that more detailed calibrations are warranted for each unit. A typical transfer function for the R-1 can be found at the manufacturer's website (<http://www.eentec.com/>, last accessed 21 January 2011). The instrument response is roughly flat from 0.05 to 20 Hz and its self noise (rms) is  $<10 \mu\text{rad/s}$  over the same frequency band.

Schreiber et al. (2011) conducted a comparison test of an R-1 rotational seismometer and a fiber optic gyro  $\mu\text{FORS}$  (Litef GmbH) at the facility of Physikalisch-Technische Bundesanstalt (PTB) in Germany (Department "Längen- und Winkelteilungen"). The two sensors were co-located at the rotation turn table that allows the precise measurements of the revolution angles and provides the time marks for calculation of the rotation rate. The authors found that the R-1 could not adequately detect low-frequency variations of rotation rate, but at frequencies above 0.1-1 Hz, its signal was quite similar to that of the  $\mu\text{FORS}$ . They concluded that "*The declared accuracy characteristics of R-1 are [according to the manufacturer, the] following: frequency bandwidth 0.033-50 Hz, resolution  $1.2 \times 10^{-7} \text{ rad/sec}$ , clip level 1 rad/sec. According to our tests, the resolution, or minimal detectable rotation rate change is about  $2 \times 10^{-5} \text{ rad/sec}$ , and the clip level is  $2.5 \times 10^{-2} \text{ rad/s}$ .*" Moreover, as found by Joachim Wassermann (personal communication, 2011), the R-1 rotational seismometer is very sensitive to temperature. The overall gain changes with increasing temperature, measured from 15 to 50 °C, by a factor of at least 30%.

The R-1 rotational seismometers recorded several hundred local earthquakes and two explosions in Taiwan (Lee et al., 2009b). The top panels in Figure 5 show the instruments deployed at station HGSD in eastern Taiwan (Liu et al., 2009). Figure 5(a) is a schematic drawing of the various seismic, geodetic, and strain instruments there, and Figure 5(b) shows the subset of the instruments deployed in the shallow vault at the left hand side of the upper drawing. These instruments include a data logger (Quanterra Q330), an accelerometer (Kinematics Episensor), a six-channel digital accelerograph (Kinematics K2 with an external rotational seismometer, R-1 by eentec), and a short-period seismometer (Mark Products L-4A). The K2+R-1 instrument is at the left hand side, and the yellow-color box is the R-1 rotational seismometer.

**Figure 5** (a) Schematic of instrument layout at station HGSD in Taiwan. (b) Photo showing the instrument vault containing a K-2 accelerograph (upper left), an R-1 rotational seismometer (yellow box), an EpiSensor accelerometer (lower right-hand side), and an L-4A short-period velocity seismometer (upper right-hand side). (c) Recorded translational accelerations (upper panel) and their spectra (lower panel) from an  $M_w$  5.1 earthquake 51 km from this site. (d) Recorded rotational rates (upper panel) and their spectra (lower panel) from the same earthquake.

The largest peak rotational rate recorded at the HGSD station (to early 2008) is from an  $M_w$  5.1 earthquake at a hypocentral distance of 51 km at 13:40 UTC, 23 July 2007. Figure 5(c) shows the amplitudes and spectra of translational accelerations recorded by the K2's accelerometer. The peak ground acceleration was  $0.47 m/s^2$  (4.8% g) and the two horizontal components have much higher peak amplitude than the vertical. Figure 5(d) shows the amplitudes and spectra for rotational rates recorded from the external R-1 seismometer. The

peak rotational rate was 0.63 mrad/s for the vertical component, which is more than twice the rotational rate recorded on either of the horizontal components. The dominant frequency band in ground acceleration is about 2–5 Hz (horizontal components), whereas for the ground rotation rate it is about 2.5–5.5 Hz for the vertical component. Other studies report observations made with the R-1 sensor and compare these point measurements of rotation to array-derived area rotations (e.g., Wassermann et al., 2009).

A new model, the R-2™, became available from eentec in 2010. As of this writing, laboratory tests on twelve R-2 units indicated that their performance did not meet the technical specifications given by the manufacturer, though the design itself appears sound (Evans et al., 2010). Other promising efforts to develop new rotational sensors include that of Northrop Grumman Lites GmbH, Freiburg, Germany, which is developing a rotational sensor specifically for seismological applications and based on fiber optic gyroscope principle, and that of ATA Sensors (Smith, 2010), which is applying an entirely different technology to develop sensors for weak motion (using a solid proof mass) and for strong motion (using their existing patented magneto-hydrodynamic, or MHD, technology).

#### 4.2.2 Laboratory calibration of rotational sensors

Most rotational sensors output a signal proportional to rotational velocity but a few produce rotational acceleration. In either case the only natural reference signal commonly available is the Earth's rotation about its pole, which is about 73  $\mu$ rad/s about the North Pole (right-handed rotation vector pointing north). While the Earth's rotation is a very useful calibration signal for weak-motion rotational sensors such as large-area ring-laser gyroscopes, it is near or below the noise level of many existing strong-motion sensors, and so is effectively unavailable for their calibration. Further, Earth rotation is a roughly 0-Hz signal ("DC"), and thus it is not useful for establishing any rotational sensor's linearity or transfer functions. Thus, strong-motion rotational sensors require the use of a precision rotational shake table, and these are costly. In what follows, we focus on calibration of strong-motion rotational sensors for which the Earth's rotation is not a viable proof signal.

In all cases, operators are advised to use a right-handed set of axes including right-handed definitions of rotational pseudovectors (e.g., Evans et al., 2009, their Figure 1). Note, of course, that many seismic instruments record in the channel order Up, North, East; so  $x$  should be thought of as East,  $y$  as North, and  $z$  as Up for the sensor to be right handed.

IEEE Standard 671-1985 (1985) provides useful guidance, while procedures specific to seismic rotational instruments are in development and will draw on both this standard and experiences at several laboratories in the early years of testing such instruments. At present, the primary concerns of those laboratories are the transfer function (response function) of rotational sensors, the self-noise levels of these sensors, and the cross-axis terms, including both rotation-to-rotation and translation-to-rotation cross-axis sensitivities. Existing works on testing rotational seismic sensors include Nigbor et al. (2009), Evans et al. (2010), Schreiber et al. (2011), and various private reports of sensor testing by the laboratories active in this field.

Transfer function. Early rotational-velocity sensors for strong-motion work have proved to be less than flat in response and to vary even in mid-band sensitivity by far more than the 1% industry norm for sensitivity accuracy. Thus, it is essential that all such sensors be calibrated individually on a shake table to determine amplitude and phase responses, from which

Laplace poles and zeros may be estimated by a parametric fit. In practice, this calibration proceeds by inputting known sine wave motions on axis with the sensor under test, and that intervals of at least three cycles of each sine frequency (preferably many more) be recorded and compared to these known inputs. Alternatively, a slowly swept sine wave spanning the same frequency band may be used. This test generally should proceed at half-octave steps in frequency from one octave below the low-frequency corner of the sensor to one octave above its high-frequency corner (some shake table systems cannot drive the sensors to this peak frequency, but one should get as high as possible without damaging the table). The sensor output and the input motions must be recorded on a common time base (ideally with simultaneous sampling to within about 10  $\mu$ s) in order to recover phase accurately. In practice, it is common to use either the positional feedback of the shake table or a reliable reference sensor to measure this input motion, so the resulting transfer function is relative to this reference signal. Empirical evidence suggests that amplitude response is best measured by comparing peak power between PSDs of the test and reference traces while phase appears to be most stably measured by cross correlation of the traces. In co-testing different instruments one should keep them near and at the same distance from the rotation point of the table to limit centrifugal inputs.

Self noise. At present, strong-motion rotational sensors appear to have self noise levels well above Earth's ambient rotational seismic background motions. The level of rotational Earth noise is not very well known at present. However, the absence of microseism-band increases in typical instrument-noise figures argues against a significant Earth-noise input. Thus, the single-sensor method of *Evans et al. (2010)* may be used until sensor noise levels drop and sensitivities rises (The same will not be true for weak motion sensors.) When that stage of sensor development is reached, there is no reason in principal not to use the two- or three-sensor methods described in that paper and works cited therein. The single-sensor method is to record sensor output with a sensitive recorder at some quiet location during a quiet interval, generally overnight. One computes the PSD and simply attributes all of it to sensor self noise. Details of a "standard" method for this computation and subsequent "operating range diagram" representation of sensor noise are given by *Evans et al. (2010)*.

Rotation-to-rotation cross-axis sensitivity. Industry norms for translation-to-translation and rotation-to-rotation cross-axis sensitivities are typically about 1%. For example, a 1-g input to a translational accelerometer oriented at right angles to that input acceleration should register no more than 0.01 g in response. The unit "g" means Earth surface gravitational acceleration, typically about 9.8 m/s<sup>2</sup>. It is a unit preferred by the earthquake engineers. This 1% norm is reasonable for seismology and earthquake engineering applications as well. That is, a rotation rate of 1 mrad/s should register on the orthogonal components as no more than a 10  $\mu$ rad/s output signal. In most sensors, imperfect alignment between the sensor case and the true active axes of the sensor dominate this cross-axis term (1% corresponds to an alignment error of about 0.6°).

Translation-to-rotation cross-axis sensitivity. It can be difficult to compare motions with differing units and fundamental physics, in this case translation and rotation, but there is a simple method that accounts for the wide anticipated use of rotational sensors for correcting tilt-induced errors in horizontal translational sensors. Tilt within Earth's gravitational field applies  $\sim 1 \mu$ g of acceleration to horizontal translation sensors for every 1  $\mu$ rad of tilt. This is a first-order sensitivity in the presence of any significant rotational motions. Thus, one should compare the output of a rotational sensor excited by translational input motions to the true translational inputs *via*  $g \sin \theta$ , where  $g$  is local gravitational acceleration and the translational sensor is rotated by an angle of  $\theta$  about a horizontal axis (i.e., tilted). Angle  $\theta$  is generally

obtained by integrating rotational velocity to rotation angle in a collocated rotational sensor. Because rotational motions in earthquakes are relatively small, perhaps 1 to 10% of translational motions when so compared, the translation-to-rotation cross-axis sensitivity of rotational sensors must be well under one part per thousand (1 PPT) in order to correct the translational sensors accurately. A similar level of immunity to translational motions is needed to make reliable use of rotational data for other purposes, such as single-site computation of surface-wave phase velocity or reducing the size of response kernels in seismic tomography. This restriction is quite stringent but has been met by well designed sensors.

#### 4.2.3 Field deployment of rotational sensors

Field deployment of rotational sensors requires site selection and preparation similar to that for any seismological instruments (Trnkoczy, et.al., 2002 and also Chapter 7 in NMSOP2). The R-1 rotational seismometer can be connected to a data logger, as with any other analog-output seismic sensor. An earlier approach in Taiwan was to connect the R-1 to a six-channel accelerograph (Kinometrics model K2) forming a six-degree-of-freedom (6-DOF) self-contained instrument. In this case, the K2 and R-1 are mounted together on a thick metal plate. A vault was constructed at the HGSD station to house this K2+R1 instrument. In addition, a six-channel, 24-bit Quanterra Q330 data logger was deployed to record ground acceleration using a Kinometrics EpiSensor and to record ground velocity using a Mark Product short-period seismometer (Model L-4A; 2 Hz natural frequency). Instruments in operation during the Phase 2 operation of Liu et al. (2009) have been shown in Figure 5 above.

Another configuration used in Taiwan is to connect an R-1 rotational seismometer directly to a 24-bit Quanterra Q330 datalogger. Data are telemetered from the field to the Institute of Earth Sciences in Taipei in real time at 20 sps (samples per second), and continuous data are also recorded on an external hard disk in the field at 100 sps. The disk is collected every three to four months when the station is being serviced. Figure 6 (on next page) shows an installation of broadband seismometer, accelerometers, and rotational sensor at the Ninganchiao station (NACB) operated by the Institute of Earth Sciences, Academia Sinica, Taiwan. Station NACB is near the back of a 60-m tunnel into a hill composed of marble, and is located at 24.1738° N, 121.5947° E, and 130 m above the sea level. This station was established in 1995 as one of the Broadband Array in Taiwan for Seismology (BAT) stations (<http://bats.earth.sinica.edu.tw/>, last accessed 21 January 2011). In April, 2008, a Model R-1 rotational seismometer of eentec and an accelerometer (Model TSA-100S of Metrozet) were installed at this site. This set of instruments forms the NAC1 station and is recorded by a 6-channel Q330 datalogger of Quanterra. In 2010, the Metrozet accelerometer was replaced by a Model AGI 520 tiltmeter.

## 5 Discussion of results and benefits of studying rotational motions

Many authors have emphasized the benefits of studying rotational motions (e.g., Twiss et al., 1993; Spudich et al., 1995; Takeo and Ito, 1997; Teisseyre et al., 2006; Trifunac, 2006; Igel et al., 2007; Fichtner et al., 2009; and Teisseyre, 2010), and its relevance to engineering applications (e.g., Trifunac, 2009; Castellani and Guidotti, 2010). Rotational seismology is also of interest to physicists using Earth-based observatories for detecting Einstein's gravitational waves (e.g., Lantz et al., 2009) because they must correct for the underlying

Earth motion (e.g., DeSalvo, 2009; Di Virgilio, 2010). Here we briefly discuss some basic issues.

**Figure 6** Photos of an installation of broadband seismometer, accelerometers, and rotational sensor at the Ninganchiao station (NACB) operated by the Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan: (a) The Ninganchiao Bridge in the National Park northwest of Hualien, Taiwan, (b) the entrance to a tunnel near the Ninganchiao Bridge, (c) the tunnel of about 60 m, leading to the Ninganchiao station, (d) the front entrance of the Ninganchiao station, (e) the recording room, showing a 6-channel Q330HR recorder to the right and the entrance to the instrument room, (f) the STS-2 broadband velocity seismometer, which is enclosed in a metal box to the right, together with two accelerometers (Model Episensor ES-T of Kinemetrics, and Model TSA-100S of Metrozet) in the middle (covered by insulation material), and a Model R-1 rotational seismometer of eentec near the bottom to the left (also covered by insulation material).

## 5.1 Linear and nonlinear elasticity

Real materials of the Earth are heterogeneous, anisotropic, and nonlinear, especially in the damaged zones surrounding faults and in poorly consolidated sediments, soil, and weathered, fractured rock near the surface. These characteristics are typical of site conditions just beneath seismic instruments, particularly for strong-motion instruments that are intended to record the sort of motions experienced by shallow-foundation structures, and in consequence, commonly are placed on the surface. In the presence of significant nonlinearity we are forced to consider the mechanics of chaos (Trifunac, 2009), and we must record both the rotational and translational components of strong motion in order to interpret such complexities.

Seismology is primarily based on the classical, linear elasticity theory, which is applicable to simple homogeneous materials under infinitesimal strain. “Curl” rotation is defined for such materials as the curl of the displacement field in Equation (2), and in this classical elasticity theory, the rotational components of motion are contained in the S waves. Meanwhile, continuum mechanics has advanced far beyond such classical theory. In particular, the elasticity theory of the Cosserat brothers (Cosserat and Cosserat, 1909) incorporates both a local rotation of continuum particles and the translational motion assumed in classical theory, as well as a couple stress (a torque per unit area) in addition to the usual the force stress (force per unit area). In the constitutive equation of classical elasticity theory for an isotropic material there are two independent elastic constants, while in Cosserat elastic theory there are at least six elastic constants. Pujol (2009) provides a tutorial on rotations in the theories of finite deformation and micropolar (Cosserat) elasticity. Twiss (2009) derives an objective asymmetric micropolar moment tensor from a discrete-block model for a deforming granular material. He also investigates seismogenic deformation associated with volumes of distributed seismicity in three different geographic areas, and finds support in the micropolar model for the effects of a granular substructure on the characteristics of seismic focal mechanisms.

Angular squeeze strain deformations were found by Gombert and Agnew (1996) for all earthquakes they studied on the basis of their experimental strainmeter data. Such squeeze circular deformations cannot be explained in a frame work of the classical continuum theory, and therefore, the authors attributed such founding to some systematic errors. However, as pointed out by Roman Teisseyre (personal communication, 2011), these deformation may exist without such errors according to the asymmetric continuum theory (Ayden et al., 1993; Teisseyre, 2010).

## 5.2 Near-field seismology

Although the observed rotational motions for teleseisms recorded in a rock vault agree well with estimates based on the classical elasticity theory (e.g., Igel et al., 2005; 2007), this is not the case for local earthquakes recorded by strong-motion installations. As first noted by Takeo (1998) and later confirmed by Lee et al. (2009b), observed rotational rates from local earthquakes are much larger than those predicted by the classical elasticity theory. For example, Bouchon and Aki (1982) determined theoretically that a maximum rotational rate of 1.5 mrad/s is expected for an M6.5 earthquake, whereas maximum rotational rates exceeding 1 mrad/s have been observed for much smaller (M4.5–5.5) earthquakes in Japan and Taiwan, for which the classical elasticity theory predicts far smaller rotations. Takeo (1998) reported the largest rotational rate to be 26 mrad/s around the north-south horizontal axis from the second largest earthquake (M5.2 at 14:09 UTC, 03 March) during the 1997 swarm, east of Cape Kawana, offshore Ito, Japan (epicentral distance ~3 km). As of the end of 2009, the

largest rotational rate recorded at the HWLB station (Hualien, Taiwan) was 2.58 mrad/s around the east-west horizontal axis for an  $M_w$  6.4 earthquake offshore that occurred at 13:02 UTC on 19 December 2009, and was located offshore at a hypocentral distance of about 49 km. The peak rotational rate was 1.57 mrad/s around the north-south axis, and 0.68 mrad/s around the vertical axis. The corresponding peak ground accelerations were 1.16, 1.85, and 0.50  $\text{m/s}^2$  for the east-west, north-south, and vertical component, respectively (5.1–18.9% g).

Figure 7 shows the vertical-axis peak rotational rate versus horizontal-axis peak ground acceleration for the earthquake data set from Takeo (2009) (top frame), and for the earthquake data set (22 August 2008 to 25 December 2009) recorded (at different distance ranges) at station HWLB, Taiwan (bottom frame; N is the number of data points).

**Figure 7** Vertical peak rotational rate (PRR) versus horizontal peak ground acceleration (PGA) for the earthquake data set from Takeo (2009) (**top frame**), and for the earthquake data set (22 August 2008 to 25 December 2009) recorded at the HWLB station, Taiwan (**bottom frame**). N is the number of data points. Best-fit lines are determined using linear least-squares. Note the difference in the scaling of the axes for the two plots.

The slopes for the two data sets (1.454 versus 0.472) are significantly different. But, as noted below, this may reflect a difference in site conditions. While the Taiwan data appears to exhibit more scatter than in the Takeo (2009) data, its variance actually is only about half. One should also note that the range of the observations in the two plots is significantly different, which may account, at least in part, for the difference in scatter. Whereas the earthquake sources for the Takeo (2009) data belong all to a compact, nearby swarm, the Taiwan data relate to widely separated earthquake sources. Several authors have noted similar linear relationships (e.g., Spudich and Fletcher, 2008; Stupazzini et al., 2009; Takeo, 2009; and Wang et al., 2009). In particular, Takeo (2009) showed “*a linear correlation between the maximum rotational displacements around vertical axis and the maximum [ground] velocities*”. The two plots in Figure 7 are equivalent to Takeo’s linear relationship, without the need to perform the integration for the measured rotational rate and ground acceleration to obtain rotational displacements and ground velocities. The linear slope in Figure 7 has units of s/km, i.e., of slowness. Spudich and Fletcher (2008) interpreted this “slowness” as the inverse of an “apparent velocity”, characterizing the seismic wavefield beneath the recording station.

Spudich and Fletcher (2008) computed peak values of ground strain, torsions, and tilts for the 2004 Parkfield earthquake ( $M_w$  6.0) and four of its aftershocks ( $M_w$  4.7–5.1) using the data recorded by the UPSAR array of accelerators. The observed peak horizontal acceleration and velocity were 0.45 g and 27 cm/s during the mainshock, and derived a maximum rotation rate of 1.09 mrad/s for the vertical component, which agrees well with the theoretical result of Bouchon and Aki (1982) mentioned above. Takeo (2009) noted that his observations of peak rotation values in the near-field region during an 1998 earthquake swarm offshore Ito, Izu Peninsular, Japan, are much larger than those calculated by Spudich and Fletcher (2008), and he proposed the following explanations: the different spatial scale of rotational motion measured by a single point gyro measurement and by an array observation (that is, the point observation not benefiting from averaging out local site variations), the effects of topography, and the difference of the degree of geologic maturation between the San Andreas fault and the swarm volume offshore Ito. Two arrays of both rotational and translational sensors have been deployed by Wu et al. (2009) in Taiwan to study this discrepancy.

### 5.3 Using explosions to study rotational motions

Because large earthquakes rarely occur near existing seismic stations, explosions have been used by several pioneers to study rotational motions (e.g., Graizer, 1991; Nigbor, 1994). Lin et al. (2009) deployed an array of eight triaxial rotational sensors, 13 triaxial accelerometers, and 12 six-channel, 24-bit data loggers with GPS time receivers to record two explosions in northeastern Taiwan. These instruments were installed at about 250 m (1 station), 500 m (11 stations), and 600 m (1 station) from the explosions. The group of 11 stations forms a “Center Array” with station spacing of about 5 m. The code name for the first shot with 3,000 kg explosives is “N3P”, and that for the smaller second shot (750 kg) is “N3”. Although the N3P shot used four times as much explosive as shot N3, the peak ground translational acceleration and rotational rates at all 13 station sites for N3P are only about 1.5 times larger than that for N3, suggesting some nonlinear process. Large variations (by tens of percent) in translational accelerations and rotational rates were observed within the small Center Array. The largest observed peak rotational rate was on the horizontal transverse component at 2.74 and 1.75 mrad/s at a distance of 254 m from the N3P and N3 shots. As pointed out by Joachim Wassermann (personal communication, 2011), this experiment may have problems with strain-tilt coupling that Lin et al. (2009) did not consider.

The acceleration data from these two explosions were used by Langston et al. (2009) to compute acceleration spatial gradients, horizontal strains and horizontal rotations, and to perform a radiometric analysis of the strong ground motion wave train. The analysis yields a complex, frequency-dependent view of the nature of seismic wave propagation over short propagation distances that imply significant lateral velocity changes in the near-surface crustal structure. Areal strain and rotation about the vertical have equal amplitudes and suggest significant wave scattering within the confines of the river valley where the experiment was performed and/or significant departure from an axisymmetric explosion source. Gradiometry shows that the P wave arrives at the array 35 degrees off-azimuth clockwise from the straight-line path and appears to have been refracted from the northern side of the valley (the shots are west of the Center Array). Chi et al. (2011) successfully recovered the first order features of vertical rotation-rate ground motions from the translational velocity waveforms in the frequency band 0.5–20 Hz by using the software of Spudich and Fletcher (2009); they deduced strain as large as  $10^{-4}$ . To fulfill the uniform-rotation assumption in the linear elasticity theory, one must use a small-aperture array. However, inverting data from an array of small spatial dimension requires accurate waveforms of high signal-to-noise ratio and high sampling rates. Since waveforms from adjacent stations are very similar, low levels of noise can have a strong influence on estimated displacement gradients. The recordings of Lin et al. (2009) were limited to 200 samples per second (sps). However, much higher sampling rates are required in the near field recording of explosions, which also radiate rather high-frequency (>100 Hz) waves.

## 5.4 Processing collocated measurements of translations and rotations

Processing collocated observations of rotation and translation is routinely performed in the inertial navigation units of aircraft and other vehicles. A similar analysis is possible for various combinations of strain components, rotations, and translations in seismology and earthquake engineering. With the exception of velocity-strain combinations (e.g., Gomberg and Agnew, 1996) these methods were largely unexplored until the recent work of Lin et al. (2010). Lin et al. demonstrated an appropriate set of these equations for earthquake engineering and seismology, and used them to recover inertial-frame displacements and rotations. Further, it is already apparent that rotational motions provide useful additional analysis opportunities — simply put, more data at a site yield more results:

Phase velocities and propagation directions. A simple calculation for non-dispersive linear-elastic plane waves with transverse polarization shows that the ratio of transverse acceleration to vertical-axis rotational velocity is proportional to local phase velocity. This result implies that information on subsurface velocity structure (otherwise only accessible through seismic array measurements and combined analyses) is contained in any single-point measurement that includes rotational sensors. It has been shown that such ratio-derived phase velocities agree with velocities predicted by theory (Igel et al., 2005; Kurrle et al., 2010). In a recent theoretical study based on full ray theory for Love waves (normal mode summation) Ferreira and Igel (2009) demonstrated that the Love wave dispersion relation also can be obtained by taking the spectral ratio of transverse acceleration to vertical-axis rotation rate. This result implies that seismic surface wave tomography is possible without requiring sub-arrays to determine local mean phase velocities. Information on the direction of propagation also is contained in the azimuth-dependent phase fit between rotations and translations. Since this fit is optimal in the direction of propagation the back azimuths can be estimated to within a few degrees (Igel et al., 2007). Linking observational translations, strains, and rotations together

also is advocated by Langston (2007) to yield a snapshot of the wavefield including direction, slownesses, and radial/azimuthal amplitude gradients independently at each such station.

Towards a new kind of tomography. The possibility of deriving local dispersion relations from single-station records leads to the question of what subsurface volume one resolves and to what degree depth-resolution velocity perturbations can be recovered. The method of choice to answer this type of question is the adjoint method (Fichtner and Igel, 2009), with which sensitivity kernels (first Fresnel zones) can be calculated to indicate the volume in which the observable parameters (typically travel times) are sensitive to structural perturbations. Fichtner and Igel (2009) introduced a new observable quantity — apparent shear wave velocity — which is a time-windowed ratio of the moduli of translational velocity and rotation angle. It turns out that sensitivity near the source vanishes, leading to a new type of resolution kernel with high sensitivity only in the vicinity of the receiver and in a somewhat smaller portion of that volume than the kernels of translational motions alone. This result implies that a superior tomographic inversion for near-receiver structures based on rotations and translations is possible. Synthetic tomographic inversions of this kind are given in Bernauer et al. (2009).

Scattering properties of the crust: Partitioning of P and S waves. The partitioning of P and S energy and stabilizing the ratio between the two is an important constraint on the scattering properties of a medium. Igel et al. (2007) discovered surprisingly great rotational energy in a time window prior to teleseismic S, belonging to the P-wave coda. Detailed analysis of the signals and modelling of wave propagation through three-dimensional random media demonstrate that these signals can be explained with P-SH scattering in the crust with scatterers of roughly 5-km correlation length and rms perturbation amplitude of 5% (the latter is better constrained). Additionally, rotation measurements can be used as a filter for SH type motion (Takeo and Ito, 1997). These results further illustrate the efficacy of rotation measurements in their own right.

## 6 Conclusions

Seismology has been very successful in vaults in the *far field* because classical elasticity theory works very well for interpreting recorded translational motions of bedrock at large distances. Because of this success and limited instrumentation options, most funding for earthquake monitoring historically has gone into global and regional seismic networks using only translational seismometers. However, to improve our understanding of damaging earthquakes we must also deploy rotational and translational instruments in the *near field* of active faults where potentially damaging earthquakes (magnitude > 6.5) occur *infrequently*. For strong-motion seismology and engineering, this requires long-term commitment to monitoring because a damaging earthquake on any given fault may not take place for hundreds of years. Given that financial resources are often limited, recording ground motions in the near field would require extensive seismic instrumentation along some well-chosen active faults and a bit of luck.

Ring laser observations at Wettzell, Germany, and at Piñon Flat, California, demonstrated consistent measurements of rotational ground motions in the *far field*. So far this success can only be demonstrated with one component of rotation. The high cost of present high-precision ring laser gyros makes widespread deployment of these instruments unlikely. Less expensive (but less sensitive) alternatives are being pursued by several academic groups (Cowsik et al., 2009; Dunn et al., 2009; Jedlička et al., 2009; Schreiber et al., 2009b;

Takamori et al., 2009; Brokesova, 2010; Kozák, 2010; and Velikoseltsev, 2010), and by commercial companies (e.g., Northrop Grumman Litef GmbH, and ATA Sensors).

Schreiber (2011, personal communication) wished to emphasize that their development of a fiber optic gyro (FOG), as reported in Schreiber et al. (2009b), has shown that FOGs are very suitable for measuring ground rotation in the near field of earthquakes, and their recent deployment of a FOG in a building on the campus of the University of Canterbury in Christchurch, New Zealand recorded clear rotational motions in November 14, 2010, from aftershocks of the 3 September 2010  $M_w$  7 earthquake nearby.

As of late 2010, only Taiwan has a modest program (Lee et al., 2009b) to monitor both translational and rotational ground motions from local and regional earthquakes at several permanent seismic stations, as well as at two arrays in a building and a nearby free-field site. These two arrays are designed to capture a repeat of the 1906 Meishan earthquake (magnitude 7.1) in the *near field* with both translational and rotational instruments in 6-DOF point and array observations (Wu et al., 2009).

Based on the developments described in the BSSA Special Issue on rotational seismology and engineering (Lee et al., 2009a), observation, analysis, and interpretation of both rotational and translational ground motions is beginning to play a significant role in seismology and earthquake engineering. An International Working Group on Rotational Seismology (IWGoRS) was organized in 2006 to promote such investigations, evaluate their implications, and share experience, data, software, and results in an open Web-based environment (Todorovska et al., 2008). Anyone can join IWGoRS at <http://www.rotational-seismology.org> (last accessed 21 January 2011), subscribe to the mailing list, and contribute to the content (publications, data, links, etc.). Finally, the Second IWGoRS Workshop (convened by Johana Brokesova and Heiner Igel) took place 10–13 October 2010 in Prague, Czech Republic (<http://www.rotational-seismology.org/events/workshops/2010/2nd-iwgors-workshop>, last accessed 21 January 2011) and included contributions from many institutions in several countries.

## Acknowledgements

We wish to thank Riccardo DeSalvo, Angela Di Virgilio, Vladimir Graizer, Jan Harms, Brian Kilgore, Jan Kozák, Ulli Schreiber, Chris Stephens, Roman Teisseyre, and Joachim Wassermann for their comments and suggestions, which greatly improve our manuscript.

## 1 Intention of this information sheet

This information sheet summarizes the most relevant considerations for the proper installation of broadband seismometers. An annotated example of proper shielding is provided as well as references to literature and internet resources.

There is no single solution to the installation of seismic stations. The best solution in your case will depend on the specific conditions of your observational sites and the targeted signals. Comprehensive discussions on seismometer installation and site selection are provided by Wielandt in Chapter 5 and by Trnkoczy et al. in Chapter 7 of this manual.

Temporary field installations for short period observations may put other demands on seismometer installation than permanent installations for broadband observations. For sensitive shortperiod observations you will primarily seek sites without local vibrational sources. High-resolution broadband observations on the other hand require careful thermal shielding and protection against air-pressure variations, since forces due to unwanted sensitivities to temperature and pressure decrease not as rapidly with increasing signal-period as the inertial forces due to ground motion do. For permanent installations you might be able to build a seismometer vault, while you have to make compromises regarding sites for temporary installations. Use the guidelines below when seeking the best solution for your specific case.

## 2 Location: site selection

- Prefer sites which are far away from noise sources like cars, industry, large buildings, tall poles (which can vibrate in the wind), room heaters and air-conditioners (which produce thermal variations), high-current power supply lines (which produce magnetic fields).
- Check whether you need a mains power supply, telephone or computer network connection, free view to the sky for GPS reception or solar panels. Site selection might be limited due to these requirements.
- Prefer subsurface locations (vaults, cellars, tunnels, underground shelters, etc). The overburden will provide thermal shielding. In addition this keeps the instruments at a distance to noise sources like air-pressure and passing cars which generate ground motion by surface loading.
- Avoid locations affected by air drafts. They will undermine your efforts to provide thermal shielding.
- If possible, your seismometer should be installed in a dedicated room all by itself.

- When selecting older cellars or cellars in estate buildings in particular for installation, be alarmed if non of the goods stored therein are placed on the ground directly. There is a potential risk of occasional flooding.

### 3 Protection

In particular for temporary installations, when usually compromises must be made during site selection, you should consider a few additional protection measures:

- **Protection against animals:** Free field installations should be protected against damage by animals. There are known cases of seismic installations being destroyed by cattle in stampede. For some unknown reason sheep and similar animals like to bite signal cables. Mice have been observed to occupy the subsurface cavity around buried seismometers building nests in the thermal insulation.
- **Protection against humans:** While it may appear obvious to protect the installation against vandalism (e.g. solar panels should be considered an attractive swag) also well-meaning persons might endanger the instruments. Loose cables on the floor are a trip hazard. Consider that curious fellows might like to pull at cables entering holes or boxes. Somebody might pull a power supply plug in the need of a free socket in good faith. All technical equipment (recorders, batteries, etc.), except the actual sensor, should be installed in a solid box which can serve as a means of transportation as well as a barrier to protect the installation.

### 4 Coupling

The best seismometer does not serve you well, if it is not rigidly coupled to the ground. You should consider the following:

- The feet of the instrument must have a stable position on the ground. Avoid rough surfaces or surfaces covered with dust or sand. Slightly hit the pier with a hammer to make the feet settle in a stable position. Strong-motion instruments should be bolted to the ground (but not broadband sensors).
- Ensure a direct coupling to the base rock. Do not install seismometers on a buried boulder. It can move independently from base rock and sometimes show resonances.
- Use concrete piers for permanent installations or deployments in unconsolidated sediments.
- In unconsolidated sediments you might prefer to bury the instrument, if the instrument is suitable for this.
- Avoid membranes. Badly coupled floors of cellars or plastic containers can tilt the instrument due to air-pressure variations. For long-period horizontal instruments you might like to install warp-free baseplates (see Chapter 5, section 5.5.3).
- Forces should only be exerted at the feet of the seismometer. Make sure that cables and insulation material cannot exert additional forces on the instrument. The cable should be lead around the seismometer in a big loop and fixed to the ground with additional weights.

## 5 Shielding

### 5.1 Unwanted sensitivities and protective shielding measures

Unfortunately seismometers are not only sensitive to inertial acceleration. You have to shield them against environmental influences which you do not like to observe. Items are sorted by priority:

**Thermal shielding** is a must. Typical coefficients of thermal expansion or temperature coefficients of suspension springs (even for thermally compensated alloys) are in the order of  $10^{-6} \text{ K}^{-1}$  to  $10^{-5} \text{ K}^{-1}$ . To resolve the signal of the permanently excited free oscillations at a level of  $10^{-12} \text{ g}$ , temperature variations of the sensing device must be kept below a level of  $10^{-6} \text{ K}$ . Therefore, wrap the instrument and containers around the instrument with a soft wool-like material or synthetic fleece which does not exert mechanical forces. In installations with high ambient humidity, synthetic fleece or polyester stuffing with stronger fibres should be preferred. Thin fibres can collect condensed ambient humidity which can result in a collapse of the spaces between fibres, thus increasing heat conductivity in the long run. Fill also gaps beneath the instrument. This prevents convective heat transport.

Further wrap the instrument with a reflective foil (available for first-aid kits) to prevent radiative heat transport.

Effective measures for thermal shielding are also subsurface installations, burying the instrument and anything which helps to prevent air drafts.

For temporary installations thermal shielding by covers made from Polystyrene have proven effective (pers. comm. Jörn Groos). Besides their positive thermal effect such covers are easy to install and can be used to protect the sensor mechanically during shipment and when burying the instrument.

**Shielding against air-pressure** variations is essential for long-period observations. Variations of the buoyancy force on the proof-mass of vertical component sensors are caused by variations of air-density due to meteorological air-pressure variations. The amplitude of such forces can easily exceed the amplitude of the tides, if the instrument is not shielded appropriately. The susceptibility to air-pressure for an unshielded seismometer pendulum made of brass and aluminium is approximately  $1500 \text{ nm s}^{-2} \text{ hPa}^{-1}$ . To resolve the signal of the permanently excited free oscillations at a level of  $10^{-12} \text{ g}$ , variations of air-pressure inside the instrument must be kept at a level below  $10^{-5} \text{ hPa}$ . Although broadband seismometers are supplied with an air-tight casing you should install an additional air-tight container with a warp-free design (see below) for highly sensitive installations. Otherwise the deformation caused by variation of air-pressure on the casing of the seismometer can result in tilt. Gravity coupled this way into the horizontal components easily exceeds inertial acceleration at large signal periods.

**Magnetic shielding** is required for high-resolution long-period observations. All temperature compensated suspension springs are susceptible to magnetic fields. For many broadband seismometers variations of the ambient magnetic field must be smaller than  $10^{-2} \text{ nT}$  to allow resolution of the permanently excited free modes. In particular at sites, where man-made magnetic fields due to large DC currents (e.g. tramway supply currents) have to be expected, a passive permalloy or active magnetic shield is advisable.

**Humidity** can cause corrosion and leakage currents. Therefore, keep your instruments dry. Use tight containers, plastic bags and desiccant to protect sensors and electronics. If you install the electronic components in a plastic bag, the excess heat of the electronics can put the surface temperature above the dewpoint.

**Electromagnetic interference** caused by strong fields must be avoided. Maintain a distance between signal cables and AC mains power cables. Use differential signal transmission wherever possible. Twisted pairs of signal cables improve immunity against electromagnetic fields. Avoid loops of signal cables which might act like pickup coils.

**Lightning induced overvoltage.** Long analog cables make your instruments vulnerable to lightning damage. Avoid long signal cables and consider to place your seismometer's feet on glass or perspex plates.

## 5.2 GRSN shielding: An illustrated and annotated case example

The sequence of Figures. 1 to 7 illustrates the shielding method commonly applied in the German Regional Seismic Network (Wielandt and Widmer-Schmidrig, 2002, GRSN). This type of shielding is now commercially available (Stoll, 2008). The GRSN is one of the most sensitive broadband networks and a comparably large number of its stations are able to detect the background free oscillation at a level of  $10^{-11} \text{ ms}^{-2}$  (Kurrle and Widmer-Schmidrig, 2006). The type of shielding used in this network is understood to be one of the essential factors to maintain this high quality.

**Figure 1** The seismometer (an STS-2 in this case; see DS 5.1) is placed on a polished gabbro plate (actually a raw gravestone obtained from a stonemason). The gabbro plate sits on three nuts or lead plates on the actual seismic pier in a subsurface vault. The gabbro plate is part of an air-pressure shield and serves as a practically non-deformable base plate. Electronic cables pass through a hole in the stone which is sealed with glue. The seismometer is aligned to north, the alignment rod points (in case of the STS-2) to east.

**Figure 2** Some kind of synthetic wool, polyester stuffing, or fleece material is gently wrapped around the seismometer. The gap between the gabbro plate and the casing of the instrument is also filled with fleece to prevent air convection. Be careful to keep the thermal insulation loosely fitting. The fleece must not exert forces on the seismometer casing.

**Figure 3** A stainless steel container (actually a large cooking pot) is placed upside down on a rubber gasket on the gabbro plate. It is screwed down onto the plate to provide an air-tight shielding. Air-pressure variations are thus attenuated by at least 40 dB. Pressure acting on the surface of the shielding may deform the steel container but not noticeably the gabbro plate. Deformations of the steel container do not affect the seismometer. This way a stable levelling of the horizontal components is maintained. It is advisable to place some desiccant inside the steel container to capture remaining humidity and reduce the risk of corrosion.

**Figure 4** A second layer of stuffing or fleece is wrapped around the steel container. Other than in this picture it is recommendable to wrap the gabbro plate too. The fleece again serves as a thermal insulation and prevents air drafts from acting directly on the surface of the instrument. Synthetic stuffing fleece with stronger fibres is preferable for this outer layer. The stronger fibres are able to maintain the structure of the fleece even when exposed to high humidity.

**Figure 5** The whole installation is wrapped with a reflective foil which can be obtained as a part of first-aid kits. The reflective foil reduces radiative and convective heat transport and therefore is part of the thermal insulation. Again it is recommended to extend the foil over the gabbro plate down to the surface of the pier. Ensure that no air-draft can pass underneath the foil. Tape it to the pier or put some heavy items on its edges.

**Figure 6** In this example an active magnetic shielding is added to the installation. The cubic frame supports three pairs of coils. A fluxgate magnetometer is used together with an active electronic feedback and the coils in order to maintain a constant magnetic field inside the cube. Such measures are recommended in magnetically polluted environments. In the case of this example the station (STU, Germany) is located in the city area of Stuttgart. The tramway produces large DC currents of varying magnitude in the subsurface. They induce magnetic fields which would be strong enough to limit the seismometer in its long-period seismic detection capability.

**Figure 7:** This picture shows the actual seismometer for station STU, which is associated with the GRSN ([http://www.szgrf.bgr.de/station\\_map.html](http://www.szgrf.bgr.de/station_map.html)) and GEOFON (<http://geofon.gfz-potsdam.de/geofon/>) networks.

## 6 Recommended readings

Scientific literature on technical aspects of seismometer installation is comparably rare. Uhrhammer and Karavas (1997) describe installation considerations at the Berkeley Seismological Laboratory. McMillan (2002) presents those of Albuquerque Seismological Laboratory. Havskov and Alguacil (2004) describe power supply and lightning protection issues besides general sensor installation topics. The effect of air pressure shielding is discussed by Zürn and Wielandt (2007). Wielandt and Widmer-Schmidrig (2002) present installation methods in the GRSN and Klinge et al. (2002) describe noise conditions achieved in this network. Holcomb *et al.* (1998) studied the positive effect of sand in borehole installations. A warp-free baseplate is described by Holcomb and Hutt (1992).

Studies of background noise conditions in existing networks can serve as a reference of what can be achieved in comparable environments. Section 7.2 of Chapter 7 may serve as an example, also for potential site selection. Peterson (1993) and Berger et al. (2004) provide reference levels for low-noise limits obtained in the Global Seismic Network. Widmer-Schmidrig (2003) demonstrates that the NLNM (Peterson, 1993; see Fig. 4.7 in Chapter 4) is biased by the STS-1 (see DS 5.1) self-noise at periods smaller than 1 mHz. Webb (2002) gives a quantitative reference of global noise conditions on land and on the sea floor as well as descriptions of typical unavoidable sources of seismic noise. Groos and Ritter (2009) provide an in-depth study of noise conditions in an urban environment.

To provide optimal conditions for seismic observations you require a basic understanding of non-seismic noise sources and how to avoid them (see, e.g., Chapter 4 as well as in Chapter 7 Fig. 7.5, Section 7.2 and Sections 7.4.3 to 7.3.5 with many Figures). Forbriger et al. (2010) provide a concise summary of considerations for high-resolution broadband installations. They further describe possible limitations due to magnetic field induced noise. Cavity effects which can amplify tilt and strain noise are studied by Emter and Zürn (1985) and Gebauer et al. (2010). Zürn and Widmer (1995) demonstrate the gravitational effect of the atmosphere on long-period vertical component observations and suggest potential countermeasures. Zürn et al. (2007) study tilt-noise induced on horizontal components by surface loading due to barometric pressure.

Do not hesitate to contact other network and station operators. Many of them will be willing to share their experience regarding seismometer installation (in particular if you are willing to share your data). A good point to start are the internet sites of major seismic networks. Some recommended sites are

<http://www.ldeo.columbia.edu/~ekstrom/Projects/WQC.html>

The Waveform Quality Center at Lamont-Doherty Earth Observatory provides routine waveform quality control results and noise level estimates for many stations in the Global Seismographic Network (GSN) which can serve as a reference for comparable installations.

<http://earthquake.usgs.gov/regional/asl/>

Albuquerque Seismological Laboratory provides the USGS Open File Reports on their website (McMillan, 2002, e.g.).

<http://seismo.berkeley.edu/>

UC Berkeley Seismological Laboratory operates the Berkeley Digital Seismic Network and other deployments and has published guidelines for the installation of seismometers (Uhrhammer and Karavas, 1997).

<http://ida.ucsd.edu/index.html>

The Project IDA operates a significant part of the Global Seismic Network. They feature quality control and low noise studies (Berger et al., 2004).

<http://geofon.gfz-potsdam.de/>

Part of Chapter 7 is a field report of the GEOFON network (<http://geofon.gfz-potsdam.de/geofon/manual/welcome.html>).

## Acknowledgements

Jörn Groos generously provided his experience with temporary installations of the Karlsruhe Broadband Array (KABBA). I am grateful to Erhard Wielandt, Walter Zürn, Rudolf Widmer-Schnidrig, and Peter Bormann for fruitful discussions and helpful comments.

## 1 The CALIBRAT system

**Note:** All programs and sub-programs with names printed below in **bold black** letters can be downloaded via the folder name **calibrat** from the listing of *Download Programs & Files* (see NMSOP-2 item **Overview** on the cover page).

The **calibrat** system consists of three programs:

**response** calculates the response function of a complete signal chain from seismometer/geophone via preamplifier and filter stages to analog or digital recorder. This response is represented as a plot of amplitude/phase versus frequency (Bode-Diagram) or as Poles and Zeros.

**caliseis** calculates missing seismometer parameters by step response, and it designs the electronic scheme of the preamplifier stage as well as the calibration inputs to the seismometer and preamplifier.

**seisfilt** designs single and complex electronic filter stages.

The **calibrat** programs as well as their manual, source code, and examples can be downloaded from the ftp-server: [ftp.gfz-potsdam.de/pub/home/dss/brib/calibrat/](ftp://ftp.gfz-potsdam.de/pub/home/dss/brib/calibrat/) or via hyperlink by right mouse click on **calibrat** in the listing *Download programs and files* (see content overview on the NMSOP-2 cover page).

or via hyperlink from the summary listing of NMSOP-2 *Download Programs & Files*. The folders with programs and program descriptions are listed there in alphabetical order of their names.

## 2 System requirements

The DOS programs are written in Turbo Pascal, and they run on any PC of IBM™ type under DOS 3.0 or higher, also in any DOS window up to Windows XP™. An independent Windows version written in Borland Delphi is under completion.

## 3 Programs

### 3.1 RESPONSE

**response** calculates Amplitude and Phase Response  
of Seismometer-and-Filter Networks  
via Parameters such as Corner Frequency, Damping, Amplification

or via Poles and Zeros  
 or via given RC-Networks applied to Operational Amplifiers

**response** stores the results on disk  
 as Parameters  
 or as Poles and Zeros  
 or as Triples of Frequency, Amplitude and Phase

**response** plots to Screen or Printer  
 Amplitude and Phase  
 versus Period or Frequency or Angular Frequency

### 3.2 CALISEIS

**caliseis** has been developed for Seismometers/Geophones with a magnet-coil transducer.

**caliseis** calculates Seismometer and Geophone Interface (electronic amplifier interface)  
 as Preamplifier, Damping and Calibration Resistor Network  
 via given Parameters  
 or via analog Time Series of the damped Seismometer  
 for given Preamplifier Output  
 and for given Calibration Sources

**caliseis** plots to screen or to Line Printer the electronic scheme  
 of Application of Damping and Calibration Network  
 to Operational Amplifier

**caliseis** prints the electronic scheme parameters  
 as Schedule of Parameters  
 and Schedule of Network Resistors

### 3.3 SEISFILT

**seisfilt** calculates Filter Parameters  
 of single stages of first or second order filters  
 or of Butterworth LOW Passes up to 32nd order  
 or of Bessel LOW Passes up to 12th order

**seisfilt** calculates and prints  
 RC-Filter Networks  
 for Operational Amplifiers

**seisfilt** stores Filter Parameters  
 as '\*.par'

The output files '\*.par' of **seisfilt** are compatible with the input files of the program **response**.

The electronic filter circuits designed by **seisfilt** can be directly connected to the preamplifier circuit designed by **caliseis**.

## Seismic Recording Systems

Günter Asch

### 6.1 Introduction

During the last ten years, recording devices based on digital technology have completely replaced their old analog predecessors. The latter are costly, require specialized maintenance and consumables, and are incompatible with computer data processing and analysis. They are no longer produced although being still in operation at many older seismological stations and network centers. They are not dealt with in this chapter. Extensive reference to analog photographic and directly visual drum recording and processing of the records is given in the chapters Instruments and Station Operation in Willmore (1979) Manual of Seismological Observatory Practice.

The technological progress in digital signal processing, data storage techniques and highly integrated digital circuits has lead to several instruments being available on the market that all fulfill the basic requirements of a seismic recording instrument and offer several more advanced features as well.

In terms of this chapter, a recording device is an autonomous, self-contained equipment, designed to measure the output signal of a sensor, digitize the signal and record it. In seismological experiments, all three components of ground movement are of interest, whereas in reflection experiments, only the vertical component up to now has been taken into account. Specialized multi-channel recorders with more than 6 channels, preferred in exploration seismics, are not covered here.

Seismic experiments vary from reflection profiles with short recording windows and high sampling rates to the continuous recording of broadband sensors with high resolution at observatories. An instrument well suited for an observatory, may be a bad choice for a wide-angle experiment and vice versa.

This chapter is a short introduction to the principal concept of seismic recording systems and should help the non-technical users to decide which instrument is suitable for their specific requirements. Fig. 6.1 gives an overview of the principal units of a seismic recording system. Each unit will be discussed in detail in the following sections.

## 6. Seismic Recording Systems

**Fig. 6.1** Principal units of a seismic recording device. Dashed boxes relate to optional functions.

## 6.2 Analog signal preparation

### 6.2.1 The Analog Signal Preparation section

The seismic sensor is connected to the Analog Signal Preparation (ASP) section. This is not only a problem of correct wiring and polarity, but depends strongly on the type of transducer used. If a passive electrodynamic sensor is used, the impedance of the recording system influences the sensitivity and the frequency of the sensor itself. The sensor's response function (see 5.2.4 to 5.2.9 and Scherbaum, 1996) have to be corrected for the input impedance of the recording device. For this type of sensor, one has to think also about the resistivity and capacity of the cable, used to connect the sensor to the recording device, in case it exceeds several tens of meters. For active sensors, i.e., all broadband sensors, the effect of the input impedance can be neglected because it does not influence the sensor's characteristic, however long cables can introduce noise into the system. In general, short shielded cables, a single common analog ground and high quality connectors help to reduce this type of noise problems. The ASP section is also responsible for protecting the sensitive electronics of the recording system against high input electrostatic voltages.

The next step in ASP is the preamplifier which, together with the Analog to Digital Converter (ADC\*), determines the resolution [counts/Volt] of the recording device. The preamplifier has to fulfill several demands, such as linearity with respect to amplitude and phase, low noise, quick recovery from overloading, i.e., no clamping, and in addition, low power consumption. In reality, there is a tradeoff between low noise and low power consumption, and the designer of the preamplifier stage has to find a compromise. In any case, the noise generated by the ASP should be distinctly lower than the least significant bit of the ADC stage. Other requirements are not as critical, but one has to take care in a system with more than one channel, that all the parts in the ASP are identical, so each channel has the same response and sampling is done simultaneously on all channels. The technical approach is explained in section 6.3.4.

-----  
\* Terms typed in Arial letters are explained in more detail in 6.7: Glossary of technical terms and links.

### 6.2.2 Analog filters

Some recorders offer a high-pass filter to remove DC-offset and long-term drifts from the measured signal. These filters are intended to mask temperature and ageing problems, related to electronic components and to the system's specific design. Users should be able to decide whether they wish to activate these filters or not. As an example, the group delay of the optional high-pass filter from a PDAS recorder is given in Fig. 6.2. The high-pass filter is formed by a simple RC-element ( $15\ \mu\text{F} \parallel 1\ \text{M}\Omega$ ) with a time constant of about 15 seconds. Signals with periods of about 3 seconds are delayed by approximately 1 sample, assuming a sampling rate of 100 Hz. For longer periods, the situation becomes worse and it is not acceptable to activate this high-pass filter to record signals from broadband sensors. From the scientific point of view, this filter makes no sense; it simply beautifies the signal and substitutes one problem for another.

**Fig. 6.2** Group delay of the optional PDAS high-pass filter.

Before converting the analog signal into counts, it has to pass a low-pass filter serving as an anti-alias filter. This limits the frequency content of the signal toward higher frequencies. The reason for this fundamental step is described in 6.3.1. In some cases, i.e., continuously integrating converters, this stage can be an integral part of the ADC itself.

## 6.3 Analog to digital conversion

Conversion of a continuous analog signal into a digital time series is based on quantization with respect to time and amplitude. Therefore it is necessary to understand the influences and limitations introduced by these two different operations. After filtering, the analog signal is sampled and converted into digital values. Since the digital domain consists only of finite length digital words, which have to represent a continuous signal, the conversion step introduces quantization errors.

### 6.3.1 Sampling theorem

The *sampling theorem* describes the effect of quantization at discrete times on an analog signal. It was first published by Shannon (1949). A simple model is given by a switch, closed periodically for a certain time. At first, this sounds quite simple but in fact, this simple device is a modulator, performing the multiplication of two signals. Fig. 6.3 shows that the output signal is the control signal of the switch, multiplied by the input signal. The control signal is a train of impulses, therefore it is periodic and can be expressed by a Fourier series:

$$P(t) = \sum_{n=-\infty}^{\infty} h \cdot \frac{\tau}{\Delta T} \cdot \frac{\sin(\pi n f_s \tau)}{\pi n f_s \tau} \cdot e^{i2\pi n f_s t}. \quad (6.1)$$

**Fig. 6.3** Relation between input-, output- and control signal of a sample device.

The variables  $h$ ,  $\tau$ ,  $\Delta T$ , and  $f_s$  are explained in Fig. 6.3, and  $\sin(\pi f_s \tau) / \pi f_s \tau$  is the Fourier transform of the  $n^{\text{th}}$  boxcar's impulse response. If we look at the sampler as an ideal device,  $\tau$  approaches 0 and therefore  $\lim_{\tau \rightarrow 0} \sin(\pi f_s \tau) / \pi f_s \tau = 1$ , i.e., a so-called Dirac impulse. The energy of a single impulse is given by  $A = h \cdot \tau$ , so the output signal is described by

$$X^*(t) = X(t) \cdot \underbrace{\frac{A}{\Delta T} \sum_{n=-\infty}^{\infty} e^{i2\pi n f_s t}}_{P(t)} \quad (6.2)$$

Due to the periodic character of the control signal  $P(t)$ , we get an infinite number of impulse responses, separated from each other by  $\Delta T = 1/f_s$  with  $f_s$  as the sampling frequency. This changes the frequency content of the measured signal, and the spectra of the input- and output signal are no longer identical. The Fourier transform of  $X^*(t)$

$$X^*(f) = \frac{A}{\Delta T} \int_{-\infty}^{\infty} (X(t) \cdot \sum_{n=-\infty}^{\infty} e^{i2\pi n f_s t}) \cdot e^{-i2\pi f t} dt \quad (6.3)$$

results in

$$X^*(f) = \frac{A}{\Delta T} \sum_{n=-\infty}^{\infty} X(f - n f_s). \quad (6.4)$$

In other words, the spectrum of the input signal is transformed into a sequence of an infinite number of spectra. All these spectra, except the one of the order 0, are called the alias spectra of  $X^*(f)$ .

To illustrate this behavior, a concrete example is given in Fig. 6.4 which demonstrates the situation with the PDAS recording system. Sampling is done with a primary sampling rate of 1 kHz. The anti-alias filters are designed as Butterworth low-pass filter of an order of 6 (36 dB/octave). The corner frequency of this filter is set at 200 Hz. Its transfer function is given by

$$H(j\omega) = \frac{1}{\sqrt{1 + (j \frac{\omega}{\omega_0})^{2n}}} \quad (6.5)$$

with  $\omega_0 = 2 \cdot \pi \cdot 200$  Hz and  $n = 6$  is the order of the Butterworth filter.

**Fig. 6.4** Alias spectra in a PDAS recording system after sampling.

The consequence of aliasing in this example is that all signals with frequencies above the so-called Nyquist frequency  $f_N = f_s / 2$  are mirrored into the spectrum of  $X(t)$  (Eq. 6.2). A signal with a frequency of 600 Hz can not be distinguished from a 400 Hz signal, and a signal with 1 kHz is seen as DC with an amplitude, depending on its amplitude and the phase difference between the signal and control signal  $P(t)$ . That is why we have to assure, by applying an anti-alias low-pass filter to the analog input time series, that its high-frequency amplitudes are drastically reduced and thus do not mirror much energy into the alias spectra. Actually, the output of the sampler  $X^*(t)$  is the summing curve of all spectra, as shown in Fig. 6.4. The spectra in Fig. 6.4 were calculated on the assumption that the PDAS recording system was fed with a white noise signal.

## 6. Seismic Recording Systems

In field seismology, very little data is collected with a sampling rate of 1 kHz. In local and regional experiments, 100 Hz sampling rate is sufficient, and for teleseismic studies even 20 Hz data are commonly used. Why does the PDAS sample at such a high frequency? One answer is that the first alias spectrum is shifted far away from the frequencies in which we are interested. A second answer is given in the next section.

### 6.3.2 Oversampling

There are several ways to describe how oversampling increases resolution. The following is adopted from a technical report published by Texas Instruments (1998). The maximum error of an ideal quantizer is  $\pm 0.5$  LSB (least significant bit). Since the input range of a  $n$ -bit ADC is divided into  $2^n$  discrete levels, each represented by an  $n$ -bit binary word, the ADC input range and the word width  $n$  are a direct measure of the maximum absolute error. In addition, the quantization step can be analyzed in the frequency domain. The number of bits representing the digital value determines the signal-to-noise ratio (SNR). Therefore, by increasing the signal-to-noise ratio, the effective resolution of the conversion will be increased. Assuming the input signal is an ever-changing signal (always true in seismology), the error caused by quantization from an ideal ADC can be viewed as a white noise signal that spreads the energy uniformly across the whole bandwidth from DC to one half of the sampling rate. The RMS amplitude of the quantization error  $U_{neff}$  is given by Tietze and Schenk (1990)

$$U_{neff} = \frac{U_{LSB}}{\sqrt{12}} \quad (6.6)$$

For a full-scale sinewave signal, the RMS amplitude for an  $n$ -bit ADC is given by:

$$U_{seff} = \frac{1}{\sqrt{2}} \cdot \frac{1}{2} \cdot 2^n \cdot U_{LSB} \quad (6.7)$$

where the factor  $1/2$  is caused by the signal having  $\pm$ maximum amplitude while the converter is from  $0 - 2^n$ . The  $1/\sqrt{2}$  comes from conversion to RMS. On the basis of Eqs. (6.6) and (6.7) the signal-to-noise ratio can be calculated

$$\begin{aligned} SNR [dB] &= 20 \log_{10} \frac{U_{seff}}{U_{neff}} \\ &= 20 \log_{10} 2^n \cdot \frac{\sqrt{12}}{2 \cdot \sqrt{2}} \\ &\approx n \cdot 6 [dB] + 1.8 [dB] \end{aligned} \quad (6.8)$$

With an ideal ADC, the quantization noise power  $P = U_{neff}^2$  is uniformly distributed across the spectrum between DC and half the sampling rate. This quantization noise power is independent of the sampling rate. If we use higher sampling rates, the noise power is spread over a wider range of frequencies. Therefore the effective noise power density at the band of interest is lower at higher sampling rates. Fig. 6.5 illustrates the effective noise power reduction in the frequency band of interest at a rate of oversampling of  $k$  and the resulting sampling rate of  $k f_s$ . One has to use digital low-pass filters to remove all frequencies above  $f_s/2$ . The effective resolution is determined by the quality of the digital filter. The remaining noise power beyond  $f_s/2$  is a measure for the quantization noise and therefore responsible for a decrease in the signal-to-noise ratio.

In an oversampled system, the sampling rate is decimated - after or during filtering - by a factor of  $k$ . In such a case, an ideal low-pass filter and decimator will reduce the quantization noise also by the factor of  $k$ . Since the signal at the band is not affected by the filter, this leads to an enhancement of the signal-to-noise ratio. The formula for the improved signal-to-noise ratio is:

$$SNR [dB] = 20 \log_{10} \left( \frac{U_{seff}}{U_{neff}} \cdot \sqrt{k} \right) \quad (6.9)$$

**Fig. 6.5** Noise power reduction in an oversampled system.

The increase of the signal-to-noise ratio and the corresponding increase in the number of bits is shown in Fig. 6.6.

**Fig. 6.6** Improvement of the signal-to-noise ratio with oversampling.

### 6.3.3 Digital filters

The concept of oversampling is strongly related to digital filters. In principal, there are two concepts available, filtering a digital data stream in the time domain. We distinguish between IIR and FIR filters. Both have their specific advantages and drawbacks and are discussed in detail by Buttkus (1991) and Scherbaum (1996). The IIR concept is adopted from analog filter design techniques and utilizes polynomial approximation to the desired transfer function. The name of this type of filter is given by the recursive design of the underlying algorithm. The FIR design is a non-causally approach, applying the time domain representation of the desired transfer function (Laplace transformation of the filter's impulse response; see 5.2.2) to the digital data stream. Both types have their specific benefits and disadvantages. On the one hand IIR filters are fast to compute, on the other hand they are not guaranteed to be stable with increasing order and, as their analog counterparts, introduce a phase shift depending on the frequency of the input signal. FIR filter are easy to implement, always stable and produce no phase shift (if expressed symmetrically). This results in a constant group delay and gives rise to small amplitude precursory artefacts at the output. A compromise getting the best from both approaches is the minimum-phase filter. A brief discussion about this problem and how to deal with is given by Scherbaum (see [http://lbutler.geo.uni-potsdam.de/FIR/fir\\_daaf.htm](http://lbutler.geo.uni-potsdam.de/FIR/fir_daaf.htm)).

All of the digital recorders available use FIR filters to decimate the digital data streams, and most of them are zero-phase filters. At the moment, only Earth Data and Kinematics (for the Quanterra records) offer minimum-phase decimation filters for their products.

### 6.3.4 Analog to Digital Converter (ADC)

The first generation of seismic recorders mainly utilized Successive Approximation Register ADCs (SAR). The concept is based on a DAC combined with a comparator and a shift register in a feedback loop.

It takes  $n$  steps to convert one sample with a binary resolution of  $n$ -bit. The right-hand part of Fig. 6.7 shows a block diagram of an SAR-ADC. In operation, the system enables the bits of the DAC one at a time, starting with the most significant bit (MSB). As each bit is enabled, the comparator gives an output signifying that the input signal is greater or less in amplitude than the output of the DAC. If the DAC output is greater than the input signal, the bit is reset, i.e., turned off. The system does this with the MSB first, then with the next most significant bit, etc. After  $n$ -steps, all the bits of the DAC have been tried, and the conversion cycle is completed. Fig. 6.7 shows the typical components and the signal flow for this type of ADC, as used for example, in the PDAS recorder. The anti-alias filter is followed by a Sample & Hold device. Using one common control signal  $P(t)$  for all Sample & Hold devices results in sampling at the same time of all input channels. Thus only one ADC device is necessary for multiple analog input channels, reducing power consumption and cost.

**Fig. 6.7** ADC concept used in the first generation of digital recording systems with a 16 bit converter.

This concept, however, has some severe disadvantages. During the conversion cycle, the input voltage must be kept stable below the resolution of the ADC. For this, and the parallel sampling of all input channels, the Sample & Hold unit and the analog multiplexer are introduced. But there is no ideal sampler with  $\lim_{\tau \rightarrow 0} \sin(\pi f_s \tau) / \pi f_s \tau = 1$  as required in Eq. (6.1). Also, the capacitor that holds the input voltage is not an ideal analog storage medium. All this together adds noise to the processed signal. But the most significant problem of this concept is the gap introduced between two Sample & Hold cycles, owing to the input signal being disconnected from the ADC.

Therefore small variations of the input signal are only taken into account if they are significant with respect to the resolution of the ADC stage. The noise reduction achieved by oversampling with this type of converter is proportional to the square root of the oversampling factor, as shown in Eq. (6.9) and Fig. 6.6.

In modern data acquisition systems, there is no clear separation any more of the **Analog to Digital Conversion** and the **Digital Signal Processing** stage, as shown in Fig. 6.1. The ADC itself does a lot of digital signal processing to achieve high resolution, high signal-to-noise ratio, and high dynamics. The used techniques are based on continuous integration and oversampling in combination with carefully designed digital low-pass filters. In most modern seismic recording systems, a Delta-Sigma-Modulator is used as ADC. A simplified block diagram of the signal flow is given in Fig. 6.8. The concept of continuously integrating the analog signal avoids gaps in the sampling process and takes into account variations of the input signal even below the resolution of the ADC. The drawback is that one has to have a separate unit for each input channel, but this is more than compensated for by having abolished the Sample & Hold- and multiplexer devices.

**Fig. 6.8** ADC concept used in most modern digital recording systems.

The scheme of a Delta-Sigma-Modulator is given in Fig. 6.9. The negative feedback from the output along the 1-bit DAC and the sum amplifier at the input is performed at a high sampling rate, transferring the quantization noise into the stop band of the digital low-pass filter used for decimation.

**Fig. 6.9** First order Delta-Sigma Modulator.

The principal elements in the block diagram of the Delta-Sigma-ADC shown in Fig. 6.9 are :

- continuously sampling integrator;
- 1-Bit A/D converter (strobed comparator);
- 1-Bit D/A converter (feedback);
- sum amplifier;
- digital low-pass filter (not shown in Fig. 6.9);

In operation, the sampled analog signal is fed to the sum amplifier, along with the output of the 1-bit DAC. The integrated difference signal is fed to the strobed comparator, whose output samples the difference signal at a frequency (the actual sampling frequency) many times that of the analog signal frequency. The output of the comparator provides the digital input for the 1-bit DAC, so the system functions as a negative feedback loop which minimizes the difference signal by tracking the input. The integrator is continuously fed with the differential signal and there are no gaps in the analog input signal, as introduced by sample and hold devices. The digital information representing the analog input voltage is coded in the polarities of the pulse train appearing at the output of the comparator. It can be retrieved as a parallel binary data word applying a digital filter operator. In general Delta-Sigma ADCs are described by the order of the integrator, which is in fact an analog low-pass filter. Fig. 6.9 shows a simple first order integrator. In real world systems, an order of four is used. This reflects a compromise between oversampling factor and stability of the modulator limited only by the performance of the analog part of the Delta-Sigma-Modulator.

### 6.3.5 Noise test

The overall noise level of a recording system can be tested by shortening the input and recording for an adequate period of time. The variation of the measured values reflects the overall noise of the recording device. This test also helps to check temperature influences and find problems in the instruments design. Loading one channel with a defined signal and cross correlating with the others, gives a detailed insight into the system's real performance.

Fig. 6.10 gives an example measured with a PDA recorder. Channel 1 was fed with a  $50\text{mV}_{pp}$  sinusoidal signal with a period of one second. Channel 2 was shortened by a  $2.5\text{k}\Omega$  resistor to simulate the output impedance of a standard passive geophone. All channels were recorded with 100 Hz sampling rate. The lower left section a) of Fig. 6.10 shows the measured signals on both channels with the left ordinate giving the  $\mu\text{Volts}$  of the input signal on channel 1 and the right ordinate the  $\mu\text{Volts}$  of the signal recorded on channel 2.

The two amplitude-spectra in Fig. 6.10 b) show a zoomed section between 0.5 to 5 Hz from a  $2^{18}$ -point FFT, calculated from a 45 minute measured record. The signals at 2, 3, 4 and 5 Hz are overtones of the signal from the signal generator. They are the result of the non-ideal sinusoidal shape of the signal generator's output, used in this test. The mean level of the spectrum of channel 1 is about one decade above the spectrum of channel 2. This shift mainly reflects the difference in resolution in the gain-ranged mode, that we used in this example. In the record of channel 1, the resolution is 30 nV/count whereas channel 2 is resolved with 4 nV/count. But one can clearly see a peak at 1 Hz in the spectrum of channel 2. Its amplitude is about 6 decades below that of the input signal on channel 1. The cross correlation between the two channels over 500 samples is shown in Fig. 6.10 c). The peak-to-peak amplitude is 0.082  $\mu\text{Volts}$ . From this, the cross coupling can be calculated as  $20 \times \log(82\text{nV}/50\text{mV}) = -115 \text{ dB}$  for this specific instrument. This is a fairly good separation of the input channels for field installations if one keeps in mind that 3-component signals measured (not only) in seismology are highly correlated.

**Fig. 6.10** Signal with 50 mV<sub>pp</sub> amplitude and 1 Hz of channel 1 of a PDA recorder and the cross coupled signal on channel 2. Shown are the a) measured signals, b) their amplitude-spectra and c) their cross correlation.

### 6.3.6 The Crystal chip set

Crystal's CS5321 analog modulator and the CS5322 digital filter function together as a high resolution ADC. Therefore they are widely used in geophysical applications. The Reftek and Güralp recording systems, as well as Nanometrics's Orion are based on this chip set. The CS5322/CS5321 combination performs sampling, A/D conversion and anti-alias filtering. The CS5321 utilizes a fourth order Delta-Sigma-Modulator architecture to produce highly accurate conversions at low power dissipation (< 100 mW). It provides an oversampled serial bit stream at 128 kBit/second ( $f_{in} = 512$  kHz, 4<sup>th</sup> order oversampling architecture) to the CS5322 FIR decimation filter. From the manufacturer's data sheet, one can compile the characteristics of the CS5322/CS5321 modulator and filter combination as shown in Fig. 6.11.

**Fig. 6.11** Dynamic range of the CS5322/CS5321 chip set ( $f_{in} = 512$  kHz).

The analog input is resolved between 20 and 22 bits, depending on the oversampling ratio  $k$ . The resolution in Fig. 6.11 is limited by the modulator, not by the filter. The CS5322 provides the digital decimation filter for the CS5321 modulator output. It is not a general purpose DSP but consists of a multi-stage FIR-filter. The decimation factor by which the oversampling frequency is reduced, is selectable from  $64\times$  to  $4096\times$ . The data at the output of the digital filter is represented in a 24-bit serial format.

The -3 dB bandwidth of each decimation rate is approximately 82% of the Nyquist frequency. The filter achieves a minimum of 130 dB signal reduction at the Nyquist frequency for all filter selections. Tab. 6.1 gives an overview of the relation of the user selectable output sampling rate  $f_{out}$  with a Reftek data logger and the associated -3 dB bandwidth of the output spectra. Due to the zero-phase FIR design of the digital decimation filter CS5322, phase shift does not depend on frequency. This results in a constant factor for the group delay.

**Tab.6.1** Selectable sampling rates, -3 dB bandwidth, and associated group delay in a Reftek system.

| $f_{out}$<br>Hz | $f_{in}$<br>kHz | $\frac{f_{in}}{f_{out}}$<br>k | -3 dB<br>Point<br>Hz | Group<br>Delay<br>sec |

| 5               | 81.92           | 16384                         | 2.1                  | 5.800                 |

## 6. Seismic Recording Systems

The CS5322 is realized as a cascade of three symmetrical FIR filters, which produce by design a constant delay of the output signal of  $29/f_{out}$  (see the manufacturer's data sheet for details of the design). The resulting group delay is given in the last column of Tab. 6.1. The software of the recording system has to shift the time stamp of a sample at the output of the filter stage by this amount of time, which the DSP needs to calculate the filtered output sample. But one has to take into account that the filter settles to full accuracy only after all filter stages have been completely recalculated, i.e., after two times the group delay, according to 57 output words. A transient signal like a step appears at the output of the DSP 29 words later. But to settle to full accuracy it will take another 28 steps. This example demonstrates that the field of application for Delta-Sigma converters is to track slowly changing signals, but not to record transient signals like spikes and steps.

### 6.3.7 The Quanterra family

The main impact in modern broadband observation was the availability of the Wielandt/Streckeisen (1972) sensor, the presentation of the doctoral thesis of Steim (1986), and the cooperation of Wielandt and Steim (1986). Steim introduced a 24-bit digitizer (US Patent 4866442) which even today gives outstanding performance. It is the de-facto standard in leading broadband experiments such as IRIS GSN, TERRAScope and GEOFON, just to name a few. Steim's digitizer is a variant of the Delta-Sigma-Modulator described in section 6.3.4, but is built up from discrete electronic parts and circuits. The main difference with respect to Fig. 6.9 is the use of a 16-bit ADC instead of the strobed comparator. The digital decimation filter is fed with a 16 bit data stream at 20 kHz. The feedback loop within the Delta-Sigma-Modulator is realized as a 1-bit stream, similar to the design shown in Fig. 6.9.

The main drawback of the original Quanterra data loggers is their rather high electric power consumption. By no means is it a portable instrument; it is designed for the installation in an observatory. These days Kinematics offers an array of Quanterra products for different kinds of application, including portables.

## 6.4 Time base

The usual thing to say about timing on all recording devices is that they allow synchronizing the internal time base against an external clock signal. With the availability of relatively cheap GPS receivers, the timing problem has been solved in a global sense. This type of time signal receivers provides a stable clock reference in the order of  $\mu$ seconds along with time, date and geographic position information, which allow synchronized data acquisition all over the world.

Moreover, the way a recording device synchronizes the internal data streams against the external clock signal differs, depending on the design goals. In active seismic field experiments, predefined time windows are recorded. The time slots vary from some tens of seconds in reflection - up to some tens of minutes in wide angle experiments. Also, in recent seismological experiments a triggered recording mode was mainly used due to limited storage capacities and computer facilities. In this mode, recording windows of several tens of minutes to hours are produced. Synchronizing a clock at the beginning of a recording window and keeping it running for several minutes up to hours will normally not produce significant drift errors. The situation becomes more complicated, if one has to synchronize a continuous

stream of data against an external clock signal. If the basic design is not done carefully, life can become a nightmare for people evaluating the data.

The standard procedure sounds quite simple. An internal clock signal is compared against an external time signal, normally the 1 pps (pulse per second) signal derived from a GPS receiver's output. From the difference in time, a control signal is derived and the internal clock is adjusted accordingly. Normally this is done by a phase locked loop in combination with a voltage controlled oscillator. All systems distinguish between two operation modes. If the difference is bigger than a selectable amount of time, the adjustment is done instantly. If everything works perfectly, the so-called jam set mode only occurs during the initializing phase of the system. While switching on the recorder, it updates the absolute time and date by reading the GPS input, and synchronizes the internal time base. During normal operation the time base advance and retard control provides the capability to adjust the internal oscillator without disturbing data acquisition. Adjustments in the order of  $\mu$ seconds per millisecond of the time base are allowed to smoothly synchronize the internal timing clocks with an external source or to simply adjust the internal clocks for known drift rates.

There are important differences in the technical realization of the clock control, resulting in quite different behaviors of the data acquisition systems. Selecting the start time of a recording window for a PDAS, an Orion, or a Güralp, results in digital data streams, starting exactly at the full second of the selected time. A Reftek or a Quanterra will start somewhere in the vicinity of the desired start time. The difference in design is quite small, but of great consequence. In an experiment with more than one instrument of these two types, each recorder samples at the same sampling rate, but at different times. A sample, related to midnight, is randomly distributed over two days on different recorders. In the case of a Reftek or a Quanterra, the ADC/DSP timing signal is derived from an internal oscillator, only providing the clock signal for the ADC/DSP unit and not synchronized by the external clock. Synchronizing is done at the output of the digital decimation filter. The PDAS, Orion, and Güralp recorders are so-called mono-oscillator systems. All timing signals are derived from a master oscillator, providing a 1 pps signal, which controls the timing of the whole recording system. This internal 1 pps signal is adjusted to zero phase with respect to the synchronizing external 1 pps clock signal and forces synchronizing of the ADC, i.e., at the input of the decimation filter. With this timing concept, all instruments in an array or on a profile, take their samples at the same time, starting at full seconds. This simplifies data acquisition of continuous data streams to a great extent.

## 6.5 Data management

### 6.5.1 Storage media

In field experiments with continuously recording instruments, one collects about 30-50 MBytes of data per day at a 3-component station with 100 Hz sampling rate. During the last years, hard disks have overcome other mass storage technologies in field recording. They have become reliable, are quite cheap, robust if switched off, their power consumption is moderate, and access is much faster than on other mass storage media. The big advantage of hard disks against other magnetic- and opto-magnetic media is the fact that they are encapsulated and insensitive in rough and dusty environments. For connecting the hard disk to the recorder, many systems support SCSI. This bus system is an accepted and well defined

## 6. Seismic Recording Systems

industry standard, available on most platforms. Up to 7 devices can be connected in parallel on a 8-bit SCSI bus and the technical specification even allows hot pluggable devices, i.e., the operator can change the hard-disc without interrupting continuous recording. With an Orion or a Güralp system, it is possible to change the hard disk without interrupting the recording process. On a PDAS this will not only result in a corrupted file system, but one also has a good chance to kill the SCSI controller chip. The only problem with SCSI hard-discs is that they are developing more and more to the high performance server market. In this market segment, low-power (and low price) is not a basic design goal. All the hard-discs fulfilling the requirements for seismic recording systems, were designed for laptops, where IDE is the standard system interface. But to swap IDE devices in a running computer system for reading or writing, ranges from tricky to impossible. So we are still waiting for the manufacturer of seismological recording systems providing us with a hot pluggable mass storage device based on low-power IDE drives and equipped with a TCP/IP connection, which would allow access to a practically unlimited number of storage media at the same time, with all the benefits of a network connection.

### 6.5.2 Data formats, compression and metadata

Even a hard disk, designed for random access, can be used as a sequential block device, just like a tape drive. The data stream is subdivided into blocks of a fixed length, including the header which defines the type of data and holds the date and time stamp of the first sample. Besides the raw data streams, state of health and status information are generated. Additional channels containing information about internal voltages, temperatures, and information related to the synchronization against the external clock are recorded.

Each subsequent block of data is written to the hard disk. No file or directory structure is necessary and it is quite easy to implement compression algorithms or ring buffer structures. Steim (1986) introduced a widely used algorithm to compress integer time series without loss of information. Blocks of data are organized in frames with a fixed length. Only the difference with respect to the first sample in the frame is stored. An associated table, occupying a 2-bit/sample within the frame, holds the information about the significant word length of the stored differential value (8-, 16- or 32-bit). The compressional rate depends on the difference between two subsequent samples, or in terms of seismology, on the noise situation of the measured signal. In general the compression rate achieved with this so-called STEIM1 algorithm is in-between 1/3 and 2/3. Steim extended this scheme introducing 4 bit differences in the STEIM2 algorithm and gaining a compression rate up to 30% against STEIM1. The Quanterra, the Orion, and the Reftek compress their data with the STEIM1 algorithm, whereas Güralp has its own compression method, but there is no principal difference.

If the block header holds two additional pointers to its predecessor and successor, this is called a tagged file system. In fact, it allows only sequential access to the data of a specific stream. Some systems like the Orion reserve a certain amount of disk space for each raw data stream. This saves the two pointers and in addition, allows an easy implementation of ring buffers. After a ring buffer is filled, the oldest data are subsequently overwritten. This user selectable behavior utilizes continuous data acquisition with a fixed length of time history. If an event in which one is interested occurs, the length of the ring buffer gives the time in which one has to access the station and download the data. Sampling 3 channels at a rate of 100 Hz, a 4 GByte hard disc will provide recording capacity for about 80 days.

To read the data into a computer system, one has only to be able to access the physical raw data device and to know the logical structure of the data frames. The big disadvantage of the frame structure with compressed data is that there is no possibility to address an item directly as recorded at a specific time. One has to read all subsequent block headers from the beginning until finally accessing the data. This storage and compression concept in seismic recording systems is optimized with respect to disk space. This is the best solution for acquiring but a bad choice for processing the data. So the first step after reading the data into a computer system, is to convert and organize it within a file system. There are several different operating systems around, and each operates with several different versions or types of file systems. If a recording system relies on a specific file system, this can become a problem for the user, who has to organize the data on a different operating system.

File systems introduce an additional abstract layer to the data model and also have their specific limitations, starting with the number of characters in a file name, up to the maximum length of a single file. The PDAS is the only recorder mentioned here writing MS-DOS<sup>TM</sup> data files directly and organizing the data streams in a hierarchical directory structure. The Orion also utilizes the same file system. If the host system is able to mount an MS-DOS<sup>TM</sup> file system, the ring buffers are visible as ordinary files.

The conclusion of all the different data formats on different recording systems is that each one needs its special treatment. The only common level at the moment is the SCSI hardware, but even this will change in future. All systems have their own way to store the data logically. Even if Steim's compression algorithm is used to write the raw data, the block header structures may differ. But this is not the real annoyance. There is no common agreement on what type of additional information is or should be recorded by the system.

Each manufacturer has his own ideas, how to synchronize against the external clock signal and how to correct the drift of the time base, and of course, how to report this. So, from here on, no general recipe for converting raw data to the user's file system can be given. Also, no recipe is available on how to treat timing errors from different data loggers (there are systems around, even reporting *unknown error*).

The user's file system normally depends on the software being run to process the data. This is the scientific part of the game and may vary from project to project. To buy an instrument from a manufacturer who is supporting only one specific operating system and withholding information about the low-level data structures, may be a bad investment.

Unfortunately, the approach to unify the low level data formats for seismic recording systems, the SUDS-2 format initialized by Ward (1992), failed because of the complexity of the abstract data model and the non-agreement on a common platform for Unix and PC-based systems. Thus, the problem handling the metadata is still unsolved. All the data describing the instrumentation and the site location related to the stored waveform are called metadata. For archiving and exchange of waveform data, there are several data formats in use, mainly, the different variants of SEG-Y and GCF (pure ASCII code), which are independent of the hardware platform and even email-proof on 7-Bit mail servers. But the most complete and widely accepted standard is the SEED format and its M-SEED variant. SEED is the only standard holding the most important metadata and the waveform data within one single file, a so-called SEED volume. M-SEED is a subset of the SEED definition, holding the waveform-data only. Thanks to the excellent software library QLIB2, M-SEED has become an easy-to-use and platform-independent data format.

## 6. Seismic Recording Systems

The software packages provided by the manufacturers are mainly reduced to set-up, quick lock, and quality check functions and are normally not intended for scientific evaluation of the data. The software should also provide converters to more common formats mentioned above. Here the GEOFON, the ORFEUS, and the PASSCAL home pages are ideal starting points to find all kinds of useful software and information.

### 6.6 Conclusions and final remarks

There is no "best" recording system available. It always depends on several aspects, which instrument to choose - and the weights are different from project to project. The requirements for a temporary installed, portable network are completely different from a permanent setup in an observatory, connected to the power supply system and the Internet. Beyond this, Delta-Sigma-Modulators with 130-140 dB and GPS-timing are state of the art, Web-hosted communication via Internet is coming up, and prices, hopefully, down. Within this chapter several products from various manufacturers are named. They are only used as examples to show specific differences in the technical realization of seismic recording systems. In fact, there are more products available but this chapter has no intention to give an overview of the market. If one particular product is not mentioned here, it is not an opinion in terms of its quality.

### 6.7 Glossary of technical terms and links

**ADC** : Analog to Digital Converter. A device that converts data from analog to digital form.

**CS5321/CS5322** : A 24-bit word-length variable bandwidth ADC. The CS5321 is a Sigma-Delta-Modulator which functions together with the CS5322 digital filter as a high resolution ADC. The CS5322/CS5321 combination performs sampling, AD conversion, and anti-alias filtering. The circuits are manufactured by *Crystal* (<http://www.crystal.com/>).

**DAC** : Digital to Analog Converter. A device which takes a digital value and outputs a voltage which is proportional to the input value.

**DSP** : Digital Signal Processor. The *big four* programmable DSP chip manufacturers are Texas Instruments, with the TMS320 series of chips; Motorola, with the DSP56000, DSP56100, DSP56300, DSP56600, and DSP96000 series; Lucent Technologies (formerly AT&T), with the DSP1600 and DSP3200 series; and Analog Devices, with the ADSP2100 and ADSP21000 series. For further information have a look at [www.bdti.com/pocket/dsp\\_guide.htm](http://www.bdti.com/pocket/dsp_guide.htm).

**Earth Data** : Earth Data Limited specializes in the research, design and manufacture of data acquisition, telemetry and 24-Bit portable recording systems ([www.kenda.co.uk/edata](http://www.kenda.co.uk/edata)) .

**FIR** : Finite Impulse Response filter, also named acausal- or, in their symmetrical realization, zero-phase-filters. For a brief description of digital filters (see Scherbaum,1996; and <http://lbutler.geo.uni-potsdam.de/service.htm>).

**Gain-ranged Mode**: A Gain Ranging Amplifier is scaling the input signal to fit the ADC's digitizing window based on signal level. This method increases the dynamic range, but not the resolution of a recording system. The resolution is limited to something less than

the number of bits available from the ADC, due to noise introduced by the uncertainties of the different gain steps. Gain-ranged mode was used in older 16-bit ADC based systems to achieve dynamic ranges up to 130 dB.

**GEOFON** : The GEOFON program of the GeoForschungsZentrum Potsdam presently operates, together with its partner organizations, 40 permanent and a varying number of longterm temporary broadband seismological stations. 30 permanent stations are located in Europe and the Mediterranean. Most of these stations are equipped with Streckeisen STS-2 very broad band seismometers and adequate Quanterra Q380 or Q4120 dataloggers (see [www.gfz-potsdam.de/geofon/index.html](http://www.gfz-potsdam.de/geofon/index.html)).

**GPS** : Global Positioning System. There are a lot of good sites to start from, for example [www.skydiversdepot.com/gps2.htm](http://www.skydiversdepot.com/gps2.htm).

**Güralp** : Güralp Systems Ltd (GSL). Manufacturer of seismometers and data acquisition systems ([www.guralp.demon.co.uk](http://www.guralp.demon.co.uk)).

**GSN** : The IRIS Global Seismographic Network. The goal of the GSN is to deploy 128 permanent seismic recording stations uniformly over the Earth's surface. These stations continuously record seismic data from very broad band seismometers at 20 samples per second. It is also the goal of the GSN to record data with a dynamic range of 140 db (24 bit digitizers). ([www.iris.washington.edu/GSN/index1.htm](http://www.iris.washington.edu/GSN/index1.htm))

**IDE** : Integrated Drive Electronics. Originally called IDE, the ATA interface was invented by Compaq around 1986. Standardized by the ANSI group X3T10 (who named it *Advanced Technology Attachment* (ATA)). Ratification in November 1990.

**IIR** : Infinite Impulse Response filter, also named causal-filter. All analog filters are of this type. For brief discription of digital filters see Scherbaum (1996).

**IRIS** : Incorporated Research Institutions for Seismology. 1200 New York Ave. NW, Suite 800, Washington, DC 20005 ([www.iris.edu](http://www.iris.edu)).

**Kinemetrics** : Kinemetrics Inc. Manufacturer of seismic sensors and data acquisition systems. (see [www.kinemetrics.com](http://www.kinemetrics.com)).

**Lennartz** : Lennartz electronic GmbH. Manufacturer of seismic sensors and data acquisition systems (see [www.lennartz-electronic.de](http://www.lennartz-electronic.de)).

**MARSLite** : The MARS recorders are an array of portable data loggers developed and manufactured by Lennartz electronic GmbH. Recent products are the MARSLite and M24 data loggers.

**Nanometrics** : Manufacturer of data acquisition systems. Nanometrics also offers complete network solutions based on satellite communication (see [www.nanometrics.ca](http://www.nanometrics.ca)).

**ORFEUS** : Observatories and Research Facilities for European Seismology. ORFEUS is the European non-profit organization that aims at coordinating and promoting digital, broadband seismology in Europe (see [orfeus.knmi.nl](http://orfeus.knmi.nl)).

**ORION** : Digital recording system, manufactured by Nanometrics.

**PASSCAL** : Program for the Array Seismic Studies of the Continental Lithosphere. PASSCAL Instrument Center, New Mexico Tech, 100 East Road, Socorro, NM 87801, U.S.A (see [www.passcal.nmt.edu/passcal/resources.htm](http://www.passcal.nmt.edu/passcal/resources.htm)).

## 6. Seismic Recording Systems

**PDAS** : Portable Data Acquisition System. Solid first generation digital recording system manufactured by Geotech/Teledyne, 3401 Shiloh Road, Garland, Texas 75041 (see [www.geoinstr.com](http://www.geoinstr.com)). This data-logger is no longer available on the market, but still widely used.

**QLIB2** : Software library available as source code (C/Fortran) from Doug Neuhauser ([doug@seismo.berkeley.edu](mailto:doug@seismo.berkeley.edu)) to read and write MSEED data files on different hardware platforms. Jewel found in the PASSCAL software distribution (Ver. 1.9) under contrib/mseed/qlib2. Unfortunately the PASSCAL routines do not profit from this library, because they used their own.

**Quanterra** : Advanced broad band remote data acquisition system. Developed by Stein (1986), it is the defacto standard in global broadband seismology. These days Kinemetrics is selling an array of Quanterra products with different specifications.

**Reftek** : Refraction Technology, Inc. 2626 Lombardy Lane, Suite 105, Dallas, TX 75220, U.S.A. (see [www.reftek.com](http://www.reftek.com)).

**SAR-ADC** : Successive Approximation Analog to Digital Converter.

**SCSI** : Small Computer System Interface. Bidirectional, parallel interface to connect up to 7 (15 with wide SCSI) external devices to a computer. ANSI-X-3T9.2 *American National Standards Institute* (see [www.ieee.org/index.html](http://www.ieee.org/index.html)).

**TCP/IP** : Transmission Control Protocol over Internet Protocol. The de facto standard Ethernet protocols. TCP/IP was developed by DARPA for internet working and encompasses both network layer and transport layer protocols. While TCP and refer to the entire DoD protocol suite based upon these, including telnet, FTP, UDP and RDP.

**TERRAscope** : is a very broadband seismographic network in Southern California. Each station consists of a Wielandt/Streckeisen seismograph, a strong-motion sensor, and a barograph. The data is recorded on-site using the 24-bit Quanterra datalogging system and collected by the Caltech Seismo Lab. ([www.gps.caltech.edu/terrascope/TerraInfo.html](http://www.gps.caltech.edu/terrascope/TerraInfo.html)).

## Acknowledgments

Reviews and suggestions by P. Bormann, J. Bribach, J. Havskov and K.-H. Jäckel have been taken into account to complement the initial draft of this paper.

## **7.1 Factors affecting seismic site quality and site selection procedure (A. Trnkoczy; version 2002)**

### **7.1.1 Introduction**

Seismic site selection is not often given the amount of study it requires. The capacity of any new seismic network to detect earthquakes and to record representative event waveforms will be governed by the signal and noise characteristics of its sites, no matter how technologically advanced and expensive the equipment used. If seismic noise at the sites is too high, many of the benefits of modern, high dynamic-range equipment will be lost. If the noise contains excessive spikes or other transients, or if man-made seismic noise is present, high trigger thresholds will be needed and result in poor network detectability. If a station is situated on soft ground, very broadband (VBB) or even broadband (BB) recording can be useless and short-period (SP) signals may be unrepresentative due to local ground effects. If the network layout is inappropriate, the location of seismic events will be inaccurate, systematically biased, or even impossible. A professional site-selection procedure is therefore essential for the success of any new seismic station or network.

It is best to begin the process of site selection by choosing, generally, two to three times as many potential sites as will finally be used. One can then study each one and choose the sites that meet as many desired criteria as possible. One may even model the performance of a few most-likely network layouts and, by comparing the results, be able to make an informed decision about which layout will best record and locate seismic events.

All parameters relevant to the site selection process are discussed here and the process is demonstrated by seeking the best locations for a six-station network around a nuclear power plant. The main goals of this particular project (Trnkoczy and Živčić, 1992) were to monitor local seismicity with a high network detectability and the ability to accurately locate local events. Thus, the placement of short-period seismometers and of surface seismic vaults were mainly, but not solely, considered.

### **7.1.2 Offsite studies**

The site selection procedure includes off-site studies and fieldwork. Off-site, or "office" studies are relatively inexpensive. They should be performed first. One can study maps and gather information about the potential sites from local and regional authorities. Once we have gathered all this information, it is likely that many potential sites will be eliminated for one reason or another. This will minimize future fieldwork and its associated costs.

A list of parameters usually included in the off-site study includes:

- geographic region of interest
- seismo-geological conditions
- topographic conditions
- accessibility

- seismic noise sources in the region
- data transmission and power considerations
- land ownership and future land use issues
- climatic conditions

#### 7.1.2.1 Definition of the geographic region of interest

The first step is defining the goals and the geographic region of interest taking both socio-economic and seismic information into account. If the main goal of the new seismic network is monitoring of the general seismicity in an entire country, this stage is greatly simplified. For other projects, one has to examine all the known major geologic faults from geological maps with a view to assess their neotectonic activity and potential, identify seismotectonic features from seismotectonic maps, if available, and compile all available information about the seismicity in the area. One has also to compile historical and instrumentally recorded events in the broader region from earthquake catalogs and other sources. The results of such a study are shown in the following figures for an area in Slovenia. Fig. 7.1 shows the broader region chosen for our example and the main geological faults within it.

**Fig. 7.1** The broader region chosen for the network in Slovenia and the main geological faults in this area (9 - Artice fault, 10 - Brestanica fault, 11 - Sava fault, 12 - Podbočje fault, 13 - Brežice fault, 14 - Orehovec fault).

Fig. 7.2 shows the distribution of earthquake epicenters as taken from seismic catalogs while Fig. 7.3 depicts the isolines of seismic energy release during the time-span of the catalogs and the hatched area finally chosen for the detailed study.

**Fig. 7.2** Earthquakes in the wider region under investigation in Slovenia. The data were compiled from all available earthquake catalogs.

**Fig. 7.3** Final choice of the area to be studied in detail by the seismic network (hatched area). Also shown are the isolines of released log-seismic energy during the time-span of the catalogs (in J/km<sup>2</sup>).

#### 7.1.2.2 Seismo-geological considerations

The underground conditions at a station influence both the seismic signal and the noise conditions and thus have a significant bearing on the potential sensitivity of a seismic station. Usually, the higher the acoustic impedance of the bedrock, the smaller the seismic noise and the higher the maximum possible gain of a station. Therefore, for each new seismic network,

one should at least prepare a map showing simplified seismo-geological conditions. One may then infer a related map in terms of acoustic impedance or bedrock quality grades with respect to their suitability for the installation of seismic recording sites. Fig. 7.4 shows an example for the region under study while Tab. 7.1 gives an example of how bedrock “quality” grades may be classified.

**Fig. 7.4** Subdivision of the region shown in Fig. 7.2 into three grades of bedrock quality. The dots mark the positions of considered station sites.

**Tab. 7.1** Classification of different types of outcropping geological formations in “quality” categories (according to R. Vidrih, personal communication 2001). Grade 5 is the best rock for seismic recordings and grade 1 is the worst.

| Grade | Type of sediments/rocks                                                                                                   | S-wave velocity   |
|-------|---------------------------------------------------------------------------------------------------------------------------|-------------------|
| 1     | Unconsolidated (Alluvial) sediments (clays, sands, mud)                                                                   | < 100 – 600 m/s   |
| 2     | Consolidated clastic sediments (sandstone, marls); schist                                                                 | 500 – 2100 m/s    |
| 3     | Less compact carbonatic rocks (limestone, dolomite) and less compact metamorphic rocks; conglomerates, breccia, ophiolite | 1800 – 3800 m/s   |
| 4     | Compact metamorphic rocks and carbonatic rocks                                                                            | 2100 – 3800 m/s   |
| 5     | Magmatic rocks (granites, basalts) ; marble, quartzite                                                                    | 2500 - > 4000 m/s |

Note: Shear-wave velocities given by engineers (e.g. Ambraseys et al., 1996) in relation to the category “bedrock” (> 750 m/s) are significantly smaller than for competent hard rock due to near surface weathering (see 7.1.3.3) and the consideration of very short wavelengths only.

### 7.1.2.3 Topographical considerations

The topography in the vicinity of a potential site has to be considered. Extremely steep mountain slopes or deep valleys may unpredictably and unfavorably influence seismic waveforms and signal amplitudes. In addition, mountain peaks are usually much more susceptible to wind-generated seismic noise, lightning strikes, and perhaps icing of the communications equipment. Therefore it is wise to avoid such locations, if possible. Sites in moderately changing topography are preferable.

The topography also has to be considered for radio-frequency (RF) telemetry networks. Establishing RF links is much simpler if hill-top sites are selected, but it is important not to let this consideration compromise the seismological considerations. (See IS 7.2 Using existing communication tower sites as seismic sites.)

#### **7.1.2.4 Station access considerations**

Seismic stations are generally located in remote areas, as far as possible away from any human activity. This can often result in relatively difficult access. Public roads do not (or should not) reach most good seismic stations and walking a considerable distance, or the use of off-road vehicles, is more or less inevitable. Inexperience in site-selection often leads to too much compromise in this respect. One needs to find a reasonable trade-off between remoteness and ease of access. Stations which are too difficult to access are expensive to establish and maintain. In consequence, they often suffer from inadequate maintenance and long repair times.

Road maps and 1:25,000 scale topographic maps usually allow an approximate estimate of the difficulties and time needed to access any potential sites. In mountainous regions both the distance from the nearest road accessible by vehicle and the elevation difference between the site and the last point accessible by vehicle are important. One should allow between 15 and 30 min of cross-country walking time for each km of distance (25 to 50 min for each mile), depending on vegetation cover, and between 20 and 30 min for each 100 m (300 feet) of height difference. Stations which require more than half an hour of cross-country walking are rare. However, one has sometimes to accept longer walking distances, particularly if RF telemetry is involved.

Seismic stations are frequently set up at existing meteorological stations. This often happens in countries which are not experienced in seismometry and especially when meteorological institutions are appointed to maintain seismic installations. Such combination of stations or network operations are not advisable, since seismological and meteorological site selection criteria are very different.

#### **7.1.2.5 Evaluation of seismic noise sources**

An assessment of man-made and natural seismic noise sources in the region from maps is only the first stage of a proper seismic noise study. It should always be followed by field measurements of the noise. Nevertheless, road and railway traffic, heavy industry, mining and quarry activities, extensively exploited agricultural areas, and many other sources of man-made seismic noise around the potential sites, along with natural sources like ocean and lake shores, rivers or waterfalls can be evaluated in a qualitative manner from the maps and by inquiry of local authorities. Willmore (1979) gives valuable information about the recommended minimum distances between the site and these types of noise sources.

Distances are given for three different sensitivities of a seismic station, two different geological conditions and both high and low seismic coupling between noise source and station site. The table is reproduced in IS 7.3 along with instructions for its use. An example for its application for the station Loma Palo Benito is given in Fig. 7.5. Nearly all the minimum distance requirements for recordings with a gain around 1 Hz of between 50,000 and 150,000 are fulfilled (the distance to the lake shore is an exception). Six criteria are not fulfilled for a gain of 200,000 or more (see shaded cells).

Note that the above guidelines were designed for 1960's technology (analog paper seismographs). They are most applicable for seismic signal frequencies above 0.1 Hz; i.e., for the medium- and high-frequency range of seismic signals. Seismic noise at lower frequencies is mainly influenced by seismo-geological and climatic conditions (see 7.1.2.8) at the recording site and much less by the seismic noise sources dealt with in the table.

#### Legend:

A - Seismic station with a gain of 200,000 or more at 1 Hz

B - Seismic station with a gain from 50,000 to 150,000 at 1 Hz

C - Seismic station with a gain of approximately 25,000 at 1 Hz

a - Source and seismometer on widely different formations or that mountain ranges or valleys intervene

b - Source and seismometer on the same formation and with no intervening alluvial valley or mountain ranges

**Fig. 7.5** Minimum recommended noise-source-to-station-site distances according to Willmore (1979) and actual distances for the seismic station Loma Palo Bonito, which is placed on hard granite rock. Shaded cells indicate that for these criteria the conditions for a class A site are not fulfilled.

Nowadays, with the ready availability of seismic recorders with a large dynamic range, it would be preferable to express the seismometer gain classes A – C in terms of the achievable minimum resolution of ground displacement or velocity amplitudes above the noise level at about 1 Hz. These would be approximately  $< 5$  nm or  $< 30$  nm/s, respectively, for class A and about 2-4 times and  $> 8$  times larger for classes B and C.

For each potential site in a network, one should determine, using maps, the actual distances of the site from relevant seismic noise sources (the extreme right column) and compare them with the recommended minimum distances. The sites which satisfy all or most of the recommendations are the best. Note, however, that local seismic noise sources like trees, buildings, fences, would require on-site evaluation. This information can be added to the table later during fieldwork.

Once we have gathered this information for all the potential sites in a network, we can draw a map, similar to that in Fig. 7.6, where all the potential sites and minimum recommended distances from known seismic noise sources are shown. The latter is achieved by drawing circles around point noise sources and bands of appropriate width along roads or railways. This gives a good overview of all the noise sources at once and helps us to see which ones and how many of them influence a particular potential seismic site.

**Fig. 7.6** Map of the seismic network region with all potential station sites (full dots) and known seismic noise sources (roads, railway, cities, villages, industrial facilities, quarries, etc) with circles of minimum recommended distances drawn around them for the case of gain 25.000 for SP seismic stations at 1 Hz set on hard clay, hardpan and similar ground, i.e., case

C b (i.e., source and seismometer on same formation and with no intervening alluvial valley or mountain range) according to Willmore (1979).

#### **7.1.2.6 Seismic data transmission and power considerations**

For radio-telemetry networks we must consider the topography within the entire network in order to design the data transmission links. Topographic maps (1:50.000 or 1:25.000) are best for this purpose. We look for a topography which enables reliable direct radio frequency (RF) links from the remote stations to the central recording site, or the minimum number of RF repeaters if topography and/or distance do not allow direct connection. More information is given in section 7.3.

If telephone lines are used for seismic data transmission, we must first check for line availability and the distances over which new lines would have to be installed. This information can be obtained from local telephone companies. New phone lines are often a significant proportion of the total cost of site preparation.

The next question concerns the power supply. If mains power is not available on site, we need to calculate the distance over which new power lines would have to be laid and the likely costs. If this is not possible, or the cost is too great, the cost for solar panels has to be evaluated.

#### **7.1.2.7 Land ownership and future land use**

During planning of a new network it is very important to clarify the ownership of the land being considered for a station and any plans for its future use. It makes no sense to undertake extensive studies if one is actually unable to use certain sites because of property ownership issues or if it appears that future development will make the site unsuitable for a seismic station. This information should be gathered from local (land ownership) and regional (future land use) public offices and authorities.

If the land is privately owned, one should contact the owner as soon as possible and make every effort to agree on a renting or purchasing contract to the satisfaction of both parties. It is very important to have "friends" rather than "enemies" around the seismic stations. In many countries this may be very important for the security of the installed equipment.

#### **7.1.2.8 Climatic considerations**

Several climatic parameters can influence seismic site selection. Regional or national meteorological surveys can provide this information. It can also be found in yearly or longer-term bulletins, which are published by nearly every meteorological institution. In developing countries it is sometimes not easy to get complete information. However, we do not need precise values for these parameters and even rough estimates can help in site selection and design of seismic shelters.

The following climatic parameters are important:

- The minimum and maximum temperatures at a site determine how much thermal insulation will be needed for the seismic vault and instruments. Temperatures below

zero degrees Celsius may cause icing of antennae. Special shielding is often required in high mountains and polar regions.

- We need to know the frequency and maximum wind speeds at sites. Wind is a major source of seismic noise, so sites with less wind are preferable to sites placed on windy mountain ridges.
- Solar data is needed to determine the minimum size required for solar panels, if they are required to provide power. The number of sunny days in the worst month and/or the longest expected uninterrupted cloudy period in a year can serve as a measure.
- The frequency and amount of precipitation (total precipitation per year and maximum precipitation per hour) will determine protection measures required to keep the vaults dry.
- In colder climates, annual snowfall levels determine how accessible a station will be during the winter, the waterproofing measures required and – if used – the optimum installation angle and size for solar panels.
- Protection against lightning is very important and has significant financial consequences. One needs to decide on what protection equipment is necessary using information on the observed frequency of lightning. Alternatively, one has to calculate how much lightning damage is likely if protection measures are not implemented. The best method for this is to obtain isokeraunic isolines, which are related to the probability of a lightning strike. This data is rarely available and it is often easier to obtain less specific but more generally available meteorological parameters – such as the annual number of days with severe thunderstorms in the area. Lightning usually varies enormously from one region to another and also varies locally, depending on the topography. Serious consideration of these parameters and the knowledge of local people on these issues are definitely worthwhile.

### 7.1.3 Field studies

Field studies are the next step in the site selection process. Expect to make several visits to each potential site. A seismologist familiar with seismic noise measurements, a seismo-geologist, and a communications expert (if a telemetry network is considered) should all visit the sites. You should allow between one and three days per site to accomplish the fieldwork. This assumes that all pertinent maps and information are available in advance and the logistics are well organized. Much also depends on a country's infrastructure and the size of the network. If the network will use RF telemetry, add an extra 20% to the time for topographical profiling and RF link calculations.

If site selection is purchased as part of the services provided by an equipment manufacturer, see IS 7.1 for a summary of the information that should be provided to them.

In general, experts visiting the sites should:

- verify the ease (in any weather) of access to the site;
- search for very local man-made seismic noise sources which might influence the site, but may not be indicated on maps (see text to Fig. 7.7);
- perform seismic noise measurements;
- study the local seismo-geological conditions;
- investigate the local RF data transmission conditions (if applicable);
- verify availability of power and telephone lines.

#### **7.1.3.1 Station access verification**

Station access should generally be possible throughout the year. However, a few days of inaccessibility due to snow or high water per year can normally be tolerated. This can be checked by talking to local people.

If non-public dirt roads are used to access the site, we need to ask about the future of these roads since roads built and owned by private, military, or forest authorities are sometimes abandoned. If there is no guarantee that such roads will be maintained in future, it is better to reposition the seismic site.

#### **7.1.3.2 Local seismic noise sources and seismic noise measurements**

During fieldwork, one should explore the vicinity of the potential site for local sources of seismic noise, usually man-made, which may not be resolvable from the available maps. A single small private "industrial" facility too close to the site may ruin its seismic noise performances completely. Local people are the best source of information.

Measuring seismic noise at the site is an important task. Seismic noise varies greatly depending on the season of the year, weather conditions, and innumerable daily occurrences. Seasonal variability of seismic noise has mainly natural causes and is clearly developed for periods,  $T$ , greater than 2 s. The variation may be as large as 20 dB at the spectral peak for ocean-storm microseisms close to  $T = 7$  s. In contrast, high-frequency noise is mostly man-made (traffic, machinery), often with a pronounced diurnal variation of the order of 10 to 20 dB. In order to accurately record all these factors, it is best to take measurements at each site over a long period of time; long enough to record a number of earthquakes. These will allow a comparison of the sites based on signal-to-noise ratio, which is the main guiding parameter for the quality of a site.

Sufficiently long measurements are often not performed for financial reasons. In such cases, some measurements are much better than none at all. Short-term measurements can not provide complete information about the noise levels at a site, but they are still very useful to identify man-made noise sources and to assess the daily noise fluctuations in the important frequency range for small local and teleseismic events (i.e. from 0.5 Hz to 20 Hz). It is important that any short-term measurements (say of 15 min duration) are carried out during specific times when maximum and minimum noise conditions are expected.

To assess the potential influence of long-term natural seismic noise variation, we should also obtain noise data from existing seismic stations in the region. If there are none of these, we have to set up one or more temporal reference stations which are not moved from site to site. By comparing noise records taken at the same time at the reference station(s) and the potential new site locations we can, at least with respect to the long-period natural seismic noise, assess the representativeness of the noise data sampled at the potential sites by scaling it to the reference site(s). This assures that any variations in natural seismic noise levels over time will not affect the comparison of different potential sites.

Records of seismic noise are usually presented as noise spectra. These can reveal more information about the type and importance of various seismic noise sources around the site than the corresponding time-domain records alone. A typical noise spectrum is shown in Fig. 7.7. We can easily see high levels of man-made seismic noise (frequencies around 15 Hz). Spectral spikes from 3 to 5 Hz shown in this spectrum originate from heavy machinery working in a quarry at 4 km distance.

**Fig. 7.7** Typical seismic noise spectrum (ground velocity power density in  $\text{m}^2/\text{s}^2/\text{Hz}$ ) at a potential seismic station site showing man-made seismic noise generated by a nearby city and heavy machinery working in a 4 km distant quarry.

However, noise spectra should never be determined without prior inspection of the original time domain records which have to be cleaned of unrepresentative spurious or transient events. Also the analysis of noise conditions should never be made on the basis of the calculated spectra alone but always in conjunction with the related time-domain records. Examples are given in sub-Chapter 7.2.

The data requirements for noise analysis depend on the type of station to be installed. For short-period stations, use noise records that are at least two minutes long to allow calculation of stable seismic noise spectra in the frequency range from 0.1 to 50 Hz. For broadband stations, use noise records that are at least twenty minutes long for noise spectra calculations from 0.01 to 50 Hz. The sampling rate should be at least 100 Hz in both cases. In order to reduce any bias due to diurnal noise variations, the measurements at the various sites should be taken at about the same time of the day. Whenever possible, use identical equipment and processing methods at all potential sites and at the reference station(s). This greatly simplifies the normalization procedure. More information about seismic noise and its measurement is given in sub-Chapter 7.2

It should be mentioned here that the assessment of seismic noise for a Very-Broad-Band (VBB) seismic station requires much more effort. Days or even months of measurement are often required to get a full picture of the seismic noise conditions at the potential site (see

Uhrhammer et al., 1998). A quiet short-period station site is not necessarily a good long-period noise site. Seismic noise may behave differently in the different frequency ranges.

### **7.1.3.3 Field study of seismo-geological conditions**

A seismo-geologist should study the geology to determine its local complexity. Uniform local underground conditions are preferred for seismic stations. The seismo-geologist should also verify the actual quality of bedrock as compared to that given in geologic maps and try to estimate the degree of weathering that local rocks have undergone. This can sometimes give a rough estimate of the depth required for the seismic vault to place the seismometers on unweathered bedrock. Unfortunately, it is often highly unreliable to judge the required vault depth in this way. At most sites only shallow seismic profiling, drilling, or actual digging of the vault can reliably reveal how deeply the rock is weathered and how deep the seismic vault must be. If shallow profiling is planned (see 7.1.3.5 below), the seismo-geologist should precisely determine the position of the profiles.

If there are local sources of high-frequency seismic noise around the site, a seismologist should carefully assess, both by inspection and measurement, to what extent they might affect recordings at the site. If the noise sources and the site are located on the same rock or soil formation, one can expect a high degree of seismic coupling between the noise source and the station. On the other hand, when the noise sources and the station are located on different geological formations with a significant impedance contrast between them, the seismic coupling is rather weak. In this case even nearby noise sources might not disturb seismic records much. The station BRG in Germany is a striking example. This is one of the best stations in the German Regional Seismograph Network (GRSN). The station is located in the middle of a busy resort town, next to a main road built on the aggraded bank of a rushing creek. The seismographs have been placed 150 m away from the road in an abandoned mining gallery which was driven horizontally from the road level into an outcropping Devonian hornschist rock cliff. Thus, the seismic sensors are well decoupled from the nearby-generated traffic noise. The site quality of BRG would correspond to B in Fig. 7.5.

### **7.1.3.4 Field survey of radio frequency (RF) conditions**

A communications expert visiting the site should examine potential obstacles to radio-wave transmission. He or she should also examine the immediate topography surrounding the site because frequently it can not be resolved from 1:50,000 scale maps, normally used in RF topographical profiling. This study needs to define the minimum required antenna height for reliable data transmission. For more information see sub-Chapter 7.3.

### **7.1.3.5 Shallow seismic profiling**

Shallow seismic profiling is usually the last step in the site selection process. It is probably the most expensive step and has usually to be contracted out to a seismic-engineering company. It should be done only at the most likely and most important sites. Shallow refraction profiles yield quantitative parameters on the rheological quality of the bedrock and enable determination of the depth of weathering. The results can determine the best position of the seismic vault as well as its required depth. One should use two approximately perpendicular

profiles, each about 100 meters long, in order to determine the seismic wave velocity (for P and/or S waves, depending on the type of source used) down to a depth of 20 to 30 meters. This is enough even for the deepest seismic vaults considered. If the seismometer is to be installed in a borehole, seismic profiling needs to penetrate to depths of about 100m, the typical maximum borehole depth.

If seismic profiling is not included in the site evaluation, most likely for financial reasons, unexpected results may occur when digging the seismic vault. One should dig until reaching bedrock and that can sometimes be unexpectedly deep. One needs to anticipate that vaults will have to be repositioned and re-dug if weathered bedrock happens to be extremely thick. This often makes the relatively high cost of profiling a wise investment. The same argument applies to boreholes, although it is easier and less costly to deepen or move a borehole than it is for a vault.

#### 7.1.4 Using computer models to determine network layout capabilities

Once we have decided on the final number of seismic stations and are very close to the final layout of the system, meaning that we have chosen two or three possible network layouts, the next useful step is to make a computer model of the network. The modeling should answer the question: Which particular network layout performs best for different aspects of network performances? One can then use these results to choose the best possible network layout for particular requirements. Among the parameters one may wish to study are:

- network detectability in terms of the spatial distribution of minimum magnitude of events which can still be recorded with a given signal-to-noise ratio (Fig. 7.8);
- precision (i.e., calculated accuracy) of event epicenter determinations in the region (Fig. 7.9);
- precision of event hypocenter determination in the region (Fig. 7.10);
- maximum magnitude of events that can be recorded without clipping (this requires an assumed gain and dynamic range of the recording equipment to be used in the network).

Note that optimal configurations for event location are often not optimal for source mechanism determination, tomographic studies or other tasks (Hardt and Scherbaum, 1994).

**Fig. 7.8** An example of computer modeling of network capabilities. Isolines of minimum magnitude of events detected at 5 seismic stations (from six in the network) with a signal-to-noise-ratio  $>20$  dB are shown for the best of the alternative network layouts.

**Fig. 7.9** An example of computer modeling of network capabilities. Isolines of uncertainty of epicenter determination in km ( $\pm 1$  standard deviation) are shown for the best of the alternative network layouts.

**Fig. 7.10** An example of computer modeling of network capability. Isolines of uncertainty of hypocenter determination in km ( $\pm 1$  standard deviation) are shown for the best of the alternative network layouts.

Several methods for direct computer calculation of optimal network configuration (layout) are described in the literature (e.g., Kijko, 1977; Rabinowitz and Steinberg, 1990; Steinberg et al., 1995). However, practical limiting conditions with respect to infrastructure, topography and accessibility usually outweigh such theoretical approaches. "Optimal" layouts calculated with these methods are rather sensitive to initial conditions such as the predicted gain of stations. This often renders results of questionable value. However, some of these programs may be of help in deciding whether to add or remove stations to an existing network (e.g., Trnkoczy and Živčić 1992; Hardt and Scherbaum 1994; Steinberg et al. 1995; Bartal et al. 2000).

A more detailed discussion of these programs is beyond the scope of this Manual. Simple methods usually suffice for our purposes because we want to compare results for various layout options. Determination of network performances in an absolute sense requires a more sophisticated approach. One program which works rather well for relative performance and which can be made available on request is described in IS 7.4: "Detectability and earthquake location accuracy modeling of seismic networks". The program is based on a simplified and uniform attenuation law for seismic waves in a homogeneous half space or in a single- or double-layer ground model. The software uses estimated uncertainties in the P- and S- wave velocities in the model and in the P- and S-phase readings. The software requires as an input the predicted sensitivity of the seismic stations in the network based on measured seismic noise amplitudes at the sites.

No matter what modeling work is carried out, choosing a seismic network layout always involves making good, educated guesses based on experience.

## **7.2 Investigation of noise and signal conditions at potential sites** (P. Bormann; version 2002)

### **7.2.1 Introduction**

The general factors affecting seismic site quality and suitable site selection procedures have been discussed above. This sub-Chapter discusses specifically the instrumental measurement of seismic noise and signals for optimal site selection, discusses specific features of noise records and spectra from different noise sources and gives recommendations for carrying out such measurements. In the following we discriminate between:

- reconnaissance noise studies prior to station site selection;
- comparison of noise and signal conditions at existing permanent stations;
- searching for alternative sites in a given network.

Examples for each case are based on data from noise surveys in Iran and Germany.

Many sites in a wide area usually have to be inspected and measured during reconnaissance noise studies, sometimes covering an entire country. Carrying out such a survey within a

reasonable time and reasonable cost often dictates making measurements with short-period instruments. These are easily and quickly deployed, require less care than long-period or broadband sensors for thermal shielding and underground tilt stability, and yield stable records immediately after installation and useful high-frequency spectra from a few minutes of recording. Many potential sites can then be measured within a day and thus quickly give a

good idea of their suitability depending on surface geology, topography, distance from potentially disturbing noise sources, etc.

However, short-term measurements using short-period seismographs do not allow judgement of the level of long-period noise ( $T > 3$  s). They are also not very suitable for assessing seasonal or diurnal variation of seismic noise. Furthermore, it is highly unlikely that during the short time windows of measurements, any signals from real seismic events will be recorded which would allow comparison of signal-to-noise-ratios (SNR) at different sites. This is important because sites with the lowest noise are not necessarily the sites with the best signal-to-noise ratio. Signal amplitudes may vary by a factor of three or more, depending on local conditions (see Figs. 4.34 to 4.36).

Nevertheless, short-period and short-term noise measurements are sufficient to get an idea of the high-frequency ( $f > 0.3$  Hz) background noise and to assess the potential influence of various types of man-made noise sources. It is also possible to assess the daily noise variability and to scale and compare measurements at the more remote sites by using a reference station at the nearest main source of man-made noise (town, factory, railway line, high way, etc.), which records throughout the investigation. In this way, we can get a reliable idea of the relative suitability of different potential sites for the frequency range of small local, regional and teleseismic events ( $0.3 \text{ Hz} < f < 30 \text{ Hz}$ ).

Existing permanent recording sites with stable recording platforms and reasonable shielding against environmental influences allow long-term comparative measurements of both seismic noise and signals in a much broader frequency band. These will give a more reliable assessment of the suitability of sites for event detection and location and also for a variety of other seismological tasks, such as source mechanism studies, tomographic studies of the Earth's structure or the use of very long-period normal modes.

If some of the sites within a seismic network are significantly noisier than others, one should look for alternative sites. For a broadband network, the measurements at alternative sites must be made with the same type of broadband sensors and with every precautions for stable installation and appropriate shielding against wind, weather and direct sunshine. The recording time at each site should be long enough to ensure proper stabilization of the sensor after installation (a few hours to days). Additional days or weeks of recording are needed for assessing diurnal noise variability and relative SNRs for local and teleseismic events.

## **7.2.2 Reconnaissance noise studies prior to station site selection**

### **7.2.2.1 Offsite assessment of expected noise levels and measurement of instrumental self-noise**

Field measurements should always be preceded by offsite studies (see 7.1.2). They help locate the most promising sites and most likely noise sources, help speed up the measurements and reduce the risk of unwanted surprise in the field and final assessment.

When geologic, environmental, climatic, settlement and infrastructure conditions indicate that sites may have very low levels then only high-performance short-period seismographs with very low instrumental self-noise should be used for noise measurements (see 5.6). The level of self-noise should be measured before going into the field and compared with the global

New Low Noise Model (NLNM) (see Fig. 5.21). The seismometer noise should be at least 6 dB below the minimum local seismic noise for the entire pass band of the sensor. The signal pre-amplification has to be set high enough to ensure that very low-level ambient noise is well resolved. The resolution of the data acquisition unit should be set at about 18 dB (3bits) below the minimum local seismic noise over the pass band of the seismograph. Clearly, the frequency response of the seismograph must be known or has to be determined beforehand (see 5.7 and 5.8 and well as the exercises EX 5.1 to 5.5).

Fig. 7.11 shows the combined frequency response of an SS-1 seismometer and an SSR-1 recorder used in field measurements for site selection in NW Iran.<sup>1)</sup> The sampling rate was 200 Hz using a 6<sup>th</sup> order low-pass filter with corner frequency  $f_c = 50$  Hz in order to avoid spectral aliasing (see 6.3.1). The filter reduces the seismograph gain between  $f_c$  and the Nyquist frequency  $f_{Ny}$  (half of the sampling frequency) in such a way that very small seismic background noise signals no longer may be resolved above the least-count digitizer noise. Correcting the noise spectrum for the decrease in seismograph gain for  $f > f_c$  results in an *apparent* increase of noise power between  $f_c$  and  $f_{Ny}$ . This is clearly to be seen in Fig. 7.12. Here, therefore, we consider only noise spectra up to 1/4 or 1/2 of the sampling frequency.

**Fig. 7.11** Amplitude and phase response curves for the seismometer-recorder combination SS-1/SSR-1 as used in field measurements in NW Iran (see Figs. 7.12 to 7.21). The response is proportional to velocity between about 1 and 50 Hz.

<sup>1)</sup> The data in Iran have been collected as part of a joint project between the International Institute of Earthquake Engineering and Seismology (IIEES) and UNDP (Ref. No.

IRA/90/009). The data relates to the seismic noise measurements at potential station sites for the Iranian National Seismic Network (INSN). The authors thank Prof. M. Ghafory-Ashtiany, President of IESSS, for the technical and staff support provided and for his kind permission to publish part of the data in this Manual.

**Fig. 7.12** Comparison of the average values (●) of the ground displacement spectrum of seismic noise recorded at the quietest site found during a noise survey in NW Iran with the equivalent displacement spectrum of the combined instrumental self-noise of the Kinemetrics SS-1 seismometer and SSR-1 data logger at a pre-amplification level of 100 times (left) and 1000 times (right). One order of magnitude difference in the amplitude spectra corresponds to 20 dB difference in the respective power spectra. In this case only the higher pre-amplification allows the resolution conditions to be met at the quietest sites in the area under investigation. Current data loggers using 24 bit digitizers connected to high output seismometers generally cover the dynamic range down to and below the low noise model. Nevertheless the use of lower output seismometers, e.g. short-period geophones, still require switchable pre-amplifications in the range of 10 to 100.

#### 7.2.2.2 Sensor installation, measurements and logbook entries in the field

Potential measurement and reference sites should be pre-selected before going into the field, based on geologic and road maps and taking into account other significant aspects or findings from preceding offsite studies. The selections may be changed during the field inspection. Essential points to be considered in field studies have already been outlined in section 7.1.3. The following complementary rules should be observed:

- take daily synchronization of the internal clocks of the data loggers used in the field and at the reference site if they have no common time reference such as GPS-controlled clocks.
- keep a log-book;

- note carefully all relevant features which characterize the measurement sites (local geology and topography, compact or weathered rock outcrop, soil type, vegetation cover, distance to settlements or industry, main roads, power lines);
- note the environmental conditions during measurement (weather, wind, rain, insolation) and the occurrence time of any transient events that might have influenced the noise record (e.g., wind gusts or cars, trains or people passing by at what distance);
- mark the position of any measurement site in your road and/or geological map;
- take representative photographs of each measurement site and sensor installation;
- whenever possible, position the seismometer directly on a flat outcropping rock surface and level it with its three adjustment screws. Unusually-long adjustment screws can be fitted to help level the sensor on rough rock surfaces (proper counter-locking of the screws ensures sensor stability);
- in the case of well-binding (clayish) soil, screw long-leg tripod adjustments directly into the soil. Alternatively, position the seismometer on a thick solid rock plate placed firmly on the ground after removing any loose gravel or vegetation (Fig. 7.13). This may be the only reliable solution when making three-component noise measurements if three individual sensors are used requiring identical installation conditions. It may also work well on rough rock surfaces as long as a nearly horizontal stable three-point support of the plate can be found. A rock plate is not necessary if the three components are mounted in the same package, e.g. for Mark L4C-3D seismometers (see DS 5.1).

**Fig.7.13** Temporary three-component reference installation in NW Iran on a leveled marble plate placed on unconsolidated ground. Two other measurement points on the horizon using outcropping hard rock are marked. The noise at the latter sites was close to the NLNM.

- in the case of wind, rain or snowfall, try to find shielding on the lee-side of a rock-face (Fig. 7.14) or bury the sensor in the ground and cover it with a tightened sheet or blanket or with a box;

- if test measurements show that noise levels are comparable for all three components in the area under investigation it is sufficient to continue the survey using only vertical component recordings. This is usually the case in isotropic noise fields, i.e. in the absence of distinct localized noise sources.
- set up at least one continuously-recording reference station in the study area in order to assess the influence of diurnal noise variations on the measurements made at different sites and at different times of the day. The reference station can be used to scale the noise records at the other sites (see Fig. 7.15).

**Fig. 7.14** Hiding with the noise recording equipment on a windy day with snowfall in a small cave on the lee-side of a rock cliff. Surface recordings under adverse weather conditions of the noise level at this site in NW Iran were close to the best sites in good weather.

- take comparative measurements at different distances are recommended to assess the reduction of noise with distance from transient sources (such as nearby road or railway traffic). Measurements on different soil conditions may also be needed if the noise also depends on the lateral impedance contrast of adjacent rock formations (see Figs. 7.16 and 7.17).
- if, at low-noise sites, the ground displacements are of the order of nm ( $10^{-9}$  m), do not stand or walk close to the sensors during the recordings. Stay at least 10 m away, remain sitting down, and keep absolutely quiet (see Fig. 7.18).
- stay several hundreds of meters away from large power lines or transformer houses. Otherwise you may get strong induction currents in the seismometer's measurement coils or record 50 to 60 Hz vibrations that are typical of large transformers or heavily loaded power lines (see Fig. 7.19).

### 7.2.2.3 Case study of noise records in the frequency range $0.3 \text{ Hz} < f < 50 \text{ Hz}$

Fig. 7.15 shows the daily noise variation at a reference site in a town in NW Iran. The noise between night and day time varies by about 20 to 30 dB around 1 Hz and by about 50 dB

around 10 Hz because of the site's proximity to a main road and poor underground conditions. Fig. 7.16 shows the large dependence of noise records and spectra on the geological underground conditions and remoteness from villages and traffic roads in the area around one of the reference stations in NW Iran .

Note that noise spectra should not be determined unless the related time domain records have been inspected and any non-representative spurious or transient events have been removed. The analysis and assessment of noise conditions should never be made on the basis of the calculated spectra alone but always in conjunction with the related time-domain records.

**Fig. 7.15** Comparison of relatively quiet sections of vertical component noise records (left; without strong transients) and related power spectra (right) at a reference site in a town in NW Iran. The measurements were made at different times of the day.

**Fig. 7.16** Noise recordings (left) and related power spectra (right) at different sites in NW Iran. From top to bottom: 1) unconsolidated Miocene terrace, 2) unconsolidated Alluvial valley fill, about 2 km away from the main road, 3) as for 2) but some 5 km away from main road; 4) outcropping volcanic hard rock near the road in a valley (with no nearby traffic at the time of measurement, 5) volcanic hard rock surface near a mountain pass road. The noise at MIA 7 is around 1 Hz very close to the global New Low Noise Model (see 4.1) and at 10 Hz only about 14 dB above it.

Fig. 7.17 shows a two minute noise record (left) and the related power spectra (right). The large amplitudes at the beginning are due to a truck and car passing by on the bumpy country road at some 100 to 400 m distance (documented by photograph and time check). Accordingly, for frequencies  $f > 7$  Hz, the noise power of the first minute of the record is 10 to 20 dB higher than for the background noise after the transient is over.

**Fig.7.17** Noise record and related spectra for the first minute (transient) and second minute (background noise). The transient is due to a truck passing by at several 100 m distance from the recording site.

Fig. 7.18 shows a recording at a remote low-noise hard rock site. The first segments are very noisy because people were "stretching their legs" only a few meters away from the sensors. This man-made noise stopped abruptly at 13:06:15 hours when they were asked to sit down and not move. Comparing the related noise power spectra for these two different record segments shows amplitudes 20 to 30 dB lower for the unspoilt ambient noise. Therefore, all members of a noise measurement crew must be instructed to stay away from the sensors and keep very quiet during measurements.

**Fig. 7.18** Noise records (left) and related power spectra (right) at a remote low-noise hard rock site in NW Iran. The large, impulse-like amplitudes in the first part of the record are due to the movement of team members near to the sensors. Note the much lower noise (dots in the spectrum) after they were asked to "sit down and be quiet".

Measurements near power lines and transformer houses likewise may significantly spoil the records. The recordings shown in Fig. 7.19 were made near a quiet countryside village. For frequencies below 13 Hz, the noise amplitudes are roughly the same in the vertical and horizontal components. At higher frequencies, surprisingly, the horizontal records are extremely noisy. The related power spectra show strong, almost monochromatic, noise peaks around 13, 30 and 50 Hz in the horizontal components. (Note that the spectral calculation stopped at the seismometer's upper corner frequency of 50 Hz; see Fig. 7.12). According to the notebook entry and site photograph the record was made only about 30 m away from a transformer house and power line. The strong monochromatic high-frequency noise peaks are probably due to strong electromagnetic induction in the horizontal measuring coils by the AC current frequency of 50 or 60 Hz and its lower harmonics (30 and 13 Hz). However, experience at other sites shows that large transformers and heavily loaded power lines may also vibrate at 50-60 Hz.

**Fig. 7.19** Noise records and related power spectra near to a transformer house and power line. Note the monochromatic spectral lines around 13, 30 and 50-60 Hz, either induced by the AC current frequency and its lower harmonics and/or caused by the vibration of the transformer.

Another experiment demonstrates the attenuation of truck-traffic noise with distance from the road and the influence of the acoustic underground impedance on the recorded spectra. In two different cases, one sensor was placed at the foot of an asphalt-covered road embankment while the other one was installed about 1 km away from the main road in the countryside. In the first case, the underground consisted of wet alluvial coastal plane deposits; in the second case, outcropping competent Cretaceous tuffaceous sandstone, i.e. a rock with a much higher acoustic impedance. The recordings were made simultaneously and the time segments analyzed when a heavy truck was passing by on the main road. On the wet alluvium the vibrations caused by a truck were recorded on the road embankment with very strong amplitudes for almost 30 seconds. Frequencies between 0.3 Hz and 20 Hz were strongly excited. Although power spectral amplitudes at 1 km distant were generally 20 to 30 dB lower, high frequencies were still clearly visible in the record and the spectrum (Fig 7.20).

**Fig. 7. 20** Comparison of seismic records and related noise spectra made at the time of passing of a heavy truck: Left: record near the road embankment; middle: record made about 1 km away from the road in the countryside (middle); right: noise power density spectra. Underground: wet Alluvial coastal plain deposits. (Note that the noise amplitudes in the left panel have been reproduced with only 40 % of the magnification in the central panel).

In contrast, Fig. 7.21 shows the records made at another section of the road embankment consisting of broken rock overlaying outcropping competent rock. A strong increase in noise amplitudes above the general background level was observed for about 5 s only, i.e., when the truck was close to the site. The general noise level, even at the time of the passing truck, was 20 to 30 dB lower than on the alluvial embankment. Also, at the broken/compact rock road embankment, spectral amplitudes for frequencies between 0.3 and 1.5 Hz were about the same as 1 km away in the side valley on the outcropping compact sandstone. On the other hand, high frequency amplitudes generated by the truck are no longer visible in the record at the hard rock site 1 km away from the main road and reduced by 20 to 30 dB in the power spectrum.

In summary, these examples show what one can expect for noise reduction with distance from main traffic roads or other sources of man-made noise, and their dependence on underground conditions. This may help guide reconnaissance field measurements for appropriate and accessible sites. The examples also illustrate the usefulness of comparing noise records in the time domain with the related power spectra in order to better identify the kind of noise sources and understand their appearance in the records.

**Fig. 7.21** As Fig. 7.20, except that records were made near a broken rock embankment of a main road and on outcropping compact tuffaceous sandstone, 1 km away in a side valley, respectively.

## 7.2.3 Comparison of noise and signals at permanent seismological stations

### 7.2.3.1 Introduction

Existing permanent seismological stations have historically been established by different institutions for different reasons and have often been installed under different underground and environmental conditions. The stations were usually operated independently, each reporting their own data readings to national or international data centers. Modern methods of data communication make it easy to link these stations, to merge them into virtual networks (see 8.4.3), to exchange waveform data in real time and to perform joint data analysis at local, national or regional data centers. The overall network performance and quality of results strongly depends on the local conditions at the individual stations. One crucial parameter is the detection threshold. This is mainly (but not exclusively) controlled by the noise conditions at the sites. High noise conditions at some stations reduces their contribution to event detection, discrimination and location accuracy of the network, may bias average network magnitude estimates and may result in inhomogeneous completeness and accuracy of earthquake catalogs. Therefore, when setting up new seismic networks or linking already existing stations into a network, a priority task should be to investigate and compare the signal-to-noise conditions at the various stations, and to find alternatives for inferior sites. Such decisions may have far-reaching consequences and involve significant cost and so should not be based on just a few short-term noise measurements in a limited frequency band. Noise measurements should be taken over at least several days, but preferably over weeks or even months, in order to get a clear understanding of the diurnal and seasonal variability of seismic noise in the full frequency band of interest for the operation of the network. Moreover, one should determine the signal-to-noise ratio (SNR) for events from different distance and azimuth ranges and compare this at existing and possible alternative sites. It is vital that all records should be made with equipment having an identical instrument response.

This is demonstrated using data from the German Regional Seismic Network (GRSN) (see Fig. 8.15). Originally the GRSN consisted of 12 sites in western Germany. Several permanent stations in eastern Germany were subsequently added to the network. The GRSN now consists of 16 digital broadband stations equipped with STS2 seismometers (see DS 5.1), 24-bit data loggers and a seismological data center at the Gräfenberg BB array center (GRFO) in Erlangen. The network covers the whole territory of Germany with a station-spacing between 80 km and 240 km. The stations are located in very different environments: e.g., near the Baltic Sea coast (HAM and LID, now BSEG; RGN); up to distances of about 700 km away from the coast (FUR); within cities (BRNL, HAM) or up to about 10 km away from any major settlement, industry or busy roads. The underground varies from outcropping Paleozoic hard rocks in Hercynian mountain areas (BFO, BRG, CLL, CLZ, GERES, MOX, TNS, WET), sedimentary rocks in areas of Paleozoic (BUG, IBBN) or Mesozoic platform cover (GRFO, STU) to unconsolidated Pleistocene (glacial) deposits (BRNL, HAM, FUR, LID, RGN). The seismometers are installed either at surface level (CLL, CLZ, HAM, IBBN, RGN, WET), in shallow vaults just a few meters below the ground surface (BUG, FUR, GSH, TNS), in boreholes (GRFO, 116 m), or in bunkers, tunnels or abandoned mines between 20 and 162 m below surface (STU, MOX, BSEG, BRG, RUE, BFO). More details about these stations and their equipment can be found on the Internet at [http://www.szgrf.bgr.de/station\\_map.html](http://www.szgrf.bgr.de/station_map.html), and <http://www.seismologie.bgr.de>.

Seismic background noise at GRSN stations varies in a wide range between the upper and lower bounds of the new global noise model (see Fig. 7.27). The noise conditions at the GRSN have been investigated in detail in the frequency range from  $10^{-2}$  to 40 Hz by Bormann et al. (1997).

### 7.2.3.2 Data analysis

Continuous recordings at all stations were systematically screened at different times of the day (0, 6, 12 and 18 hrs UT) in order to reveal diurnal variations and their site dependence. Records were also monitored throughout the year in order to identify periods of minimum and maximum noise level and their seasonal variations. Respective record sections and related power spectral densities (PSD) were plotted together and checked for transient signals from seismic or other spurious events.

Data of the GRSN are acquired at a sampling rate of 80 Hz for most stations and 20 Hz at the more noisy stations. For most of the routine noise analysis, the 80 Hz data were re-sampled at 20 Hz. The Power Spectral Density (PSD) was calculated using a subroutine from the program SEIS89 (Baumbach 1999). It implements, in a somewhat modified form, an algorithm recommended as a standard for the calculation and presentation of noise spectra by the Ad Hoc Group of Scientific Experts (1991). The modification allows the use of segments of data larger than 512 samples, thus permitting the analysis of more long-period noise. The digital time series containing background noise are divided into a number of half-overlapping record segments, normally of 4096 samples. The power spectra are then calculated for each segment (after removing the mean and tapering the ends of each segment with a sine-cosine window) and then averaged over eight segments in order to reduce the variance of the PSD estimate. Accordingly, the presented power spectra are representative for noise records of about 15.4 min duration in case of 20 s.p.s. and of about 3.8 min duration for 80 s.p.s.. All spectra are corrected for the instrument response. The power spectra are presented in units of displacement power spectral density in  $\text{nm}^2/\text{Hz}$ . A lower frequency limit is imposed such that the longest period which can be analyzed using this procedure is one sixth of the segment length.

According to Fig. 7.48 in section 7.4.4, STS2 seismographs have a self-noise which is below the global New Low-Noise Model between about  $10^{-3}$  Hz and 10 Hz. According to Wielandt and Zürn (1991), they can resolve the noise at BFO, which is one of the quietest seismic stations in Germany, for frequencies below 30 Hz. Thus, instrumental and/or digitization noise can potentially affect the noise estimates at the best sites only at frequencies above and below this range.

Essential results of the analysis are presented below. Figs. 7.22 - 7.37 are reproduced from Journal of Seismology, Vol. 1, 1997, pp. 357-381, "Analysis of broadband seismic noise at the German Regional Seismic Network and search for improved alternative station sites" by P. Bormann, K. Wylegalla and K. Klinge, Figures 2, 4, 6-7, 9, 11-15, 17-20 and 22; © 1997( with kind permission from Kluwer Academic Publishers).

### 7.2.3.3 Results

Fig. 7.22 shows an example of high-pass filtered short-period Z-component records of seismic background noise from 15 stations of the GRSN. Amplitudes differ by more than one order of magnitude. Noise amplitudes on vertical and horizontal recordings were about the same at any given station. Therefore, only spectra from Z-component records are considered. In long-period records, however, horizontal noise is sometimes significantly larger (e.g., for stations RGN and BSEG in Fig. 7.23), due to the high tilt sensitivity of long-period horizontal seismometers (see 5.3.3).

**Fig. 7.22** High-pass filtered ( $f_c = 0.7$  Hz) Z-component noise records of GRSN stations on July 30, 1996, at night time (from Bormann et al., 1997).

On very calm days at stations with very good environmental shielding (e.g., BFO, GRFO, TNS in Fig. 7.23), horizontal long-period noise might be equal to or only somewhat stronger than in vertical components. On stormy days with high wind pressure fluctuations and related tilts, however, the noise power in near-surface horizontal recordings might be 20 to 30 dB higher than in vertical ones. When the sensors are installed sufficiently deep in boreholes (as GRFO; 116 m below surface) or in mines (as BFO; 162 m below surface) this difference will be much less, even during stormy days.

**Fig. 7.23** Three-component recordings at five GRSN stations after applying a long-period SRO filter characteristic (from Bormann et al., 1997).

Differences in the displacement PSD at the GRSN stations are most obvious for frequencies above 0.5 Hz. They may reach about 60 dB (Fig. 7.24) and are due to the varying proximity to man-made noise sources and differences in underground conditions. The stations BRNL (Berlin Lankwitz) and HAM (Hamburg) proved to be the worst sites. For longer periods ( $T > 2$  s) the differences in noise level between the GRSN stations are much less pronounced; less than 10 dB in most cases. However, over a long period of time (Fig. 7.25) the noise power variability at individual stations of the GRSN proved to be smallest (and seasonally independent) around  $f = 1$  Hz (about 5 to 10 dB variation only). It is larger between 2 to 10 Hz (up to about 20 dB) and largest for the secondary ocean-storm microseism peak around 7 s period (30 to 40 dB). Microseisms only occur episodically and with seasonally varying intensity (strongest at the time of winter storms). At periods around 20 s, the range of noise power variations still reaches 20 to

30 dB. This is equivalent to variations in the magnitude threshold for  $M_s$  determinations of up to 1.5 magnitude units.

**Fig. 7.24** Displacement power density spectra at selected GRSN stations determined from noise records on the morning of April 13, 1993. For comparison the ranges of noise power observed at the new sites BSEG, RGN and RUE are given as shaded areas (from Bormann et al., 1997).

**Fig. 7.25** Comparison of the minimum and maximum levels of short-period and long-period seismic noise power observed at GRSN stations (modified after Friedrich, 1996; from Bormann et al., 1997).

Fig. 7.26 shows record sections of only 1 minute duration and with identical gain for one of the quietest and one of the noisiest days observed during a year at each of the stations MOX and HAM. The amplitudes of secondary ocean-storm microseisms with periods of about 6 to 7 s, on the noisy day, are at HAM only about twice as large as at MOX despite HAM being much closer to their origin along the European North Atlantic coastline. On the other hand, the high-frequency noise at HAM is always much larger than at MOX. The corresponding displacement power spectra for the quietest day at MOX (May 23) and the noisiest day at HAM (January 13) during 1993 are compared in Fig. 7.27 with the global New Low Noise Model (NLNM) and New High-noise Model (NHNM) according to Peterson (1993).

**Fig. 7.26** Comparison of record segments with largest (13 January) and lowest seismic background noise (23 May) observed in 1993 at stations HAM (upper two traces) and MOX (lower two traces) (from Bormann et al., 1997).

**Fig. 7.27** Spectra for the noisiest day observed at HAM (January 13) and the quietest day at MOX (May 23) during 1993. The NHNM and NLNM according to Peterson (1993) are shown for comparison. The shaded area (1) covers the range of short-period noise power calculated by Henger (1995) for all GRSN stations on March 1, 1994 (modified from Bormann et al., 1997).

The diurnal variations of man-made noise have also been investigated at all stations of the GRSN. The variations are very distinct (20 to 30 dB) at the stations BRNL, BUG and FUR, i.e. at sites in densely populated areas and with thick unconsolidated subsoil. They are much less (< 5 to 10 dB) at stations on hard rock in smaller and less busy towns (such as BRG and CLZ) or even at several km distance to the nearest villages (CLL, MOX and TNS).

Due to the large differences in noise conditions at the GRSN stations, the capability to detect and locate events with at least 3 stations was rather inhomogeneous over German territory. The detection thresholds ranged between  $M_l = 1.5$  and 3. Since the network was supposed to detect and localize all local events with  $M_l \geq 2$ , more suitable sites had to be found for some stations. This was particularly true for BRNL and HAM. The search for more appropriate alternative sites focused on areas not too far away from these stations in order to preserve the general configuration of the GRSN.

## **7.2.4 Searching for alternative sites in a given network**

### **7.2.4.1 Geological and infrastructure considerations**

We consider here two case studies for replacing the seismic stations BRNL and HAM.

BRNL was located on the courtyard of the Geophysical Institute of the Free University of Berlin, about 12 km from the city center. The station underground consists of about 290 m unconsolidated Cenozoic sediments overlaying a thick sequence of Mesozoic sedimentary rocks. These unfavorable underground conditions, together with high population and nearby traffic density, made this station one of the noisiest in Germany. An alternative site had to be found in the wider surroundings of Berlin.

In the area of Berlin, the base of the Permian Zechstein subdivision is between about 2600 m and 4000 m below sea level. The pre-Permian basement is block-faulted with different vertical movements between adjacent blocks during post-Permian times. This mobilized the overlying plastic salt deposits of the Zechstein subdivision and resulted in the formation of dozens of salt-pillow structures, up-doming the Mesozoic sequences above. In a few cases, salt diapirs pierced through the post-Permian deposits to the present surface. The largest of these halokinetic structures exists beneath the small town of Rüdersdorf (Fig. 7.28) about 25 km east of the city center of Berlin. It was exposed by Pleistocene glacial erosion, thus forming the northernmost natural outcrop of Middle Tertiary limestones in Germany which has been mined for hundreds of years. Logistically, Rüdersdorf is easy to reach and has all the power and telecommunication connections needed for a GRSN station. The open-cast development stretches E-W and is about 0.5 to 4 km away from the eastern segment of the busy "Berliner Ring Autobahn" (motor highway). Despite the proximity to town and highway and the continuing surface mining in the quarries of Rüdersdorf, this area was considered to be the most promising alternative for the station BRNL both from a seismo-geological and logistical point of view. This was subsequently confirmed by measurements (see 7.2.4.3).

Hamburg is situated in the NW of the North German-Polish Depression. The regional geological conditions are similar to those around Berlin although the depression is much deeper here. The unconsolidated sediments above the basis of Tertiary are about 1.5 km thick beneath the station. HAM was situated about 12 km away from the city center but rather near ( $< 1$  km) to different segments of the dense highway network. Accordingly, the noise conditions were the worst of all the seismic stations in Germany. The most promising alternative site was on an outcropping, partially mined, salt diapir in the town of Bad Segeberg, about 50 km NNE from the center of Hamburg, not too close to either the North Sea or Baltic Sea, easily accessible and with suitable infrastructure and communications facilities. There are Quarternary unconsolidated sediments, about 100 to 400 m thick, and Cretaceous and Triassic sedimentary rocks at a few hundred meters depth, adjacent to the diapir. Fig. 7.29 shows a schematic cross section through the former castle hill and the upper few hundred meters of the diapir of Bad Segeberg.

**Fig. 7.28** Cross sections through the salt-tectonic up-doming at Rüdersdorf at local (above) and regional scale (below) (from Bormann et al., 1997).

**Fig. 7.29** Cross-section through the former castle hill of Bad Segeberg (above) and the related geological profile of the Permian salt diapir (below) (from Bormann et al., 1997).

#### 7.2.4.2 Recording conditions and data analysis of temporary noise measurements for alternative permanent broadband stations

Identical very broadband STS2 seismometers were used with PDAS digital data loggers for comparative measurements of seismic background noise at BRNL and with their potential alternative station sites RUE and BSEG. The data were sampled at 100 Hz. The seismometer at RUE was placed in a small tunnel in the quarry in order to reduce the influence of temperature

variations and to enable stable broadband recordings. The tunnel was about 10 m long, with 55 m of limestone overburden, and the site was 2 to 3 km away from the highway and the village of Rüdersdorf. At BSEG, the STS2 was installed in a gypsum cave within the diapir caprock of Bad Segeberg, about 20 to 30 m below the surface. The cave is only a few hundred meters away from the town center of Bad Segeberg.

In both cases the instruments were placed directly on a levelled hard rock surface. No additional thermal or pressure shielding was provided during the temporary measurements apart from the manufacturer's standard metallic sensor platform with cover hood. Therefore, in the data shown below, the long-period noise at RUE and BSEG is higher than it would be in a good permanent installation. Note that in contrast to temporary noise measurements with short-period seismometers, broadband sensors require about one day to adapt to the environmental conditions and find a stable zero position. Meaningful data can only be acquired after this.

For several days, continuous noise and signal measurements were carried out at BSEG and RUE parallel to HAM and BRNL, respectively. Data sampled at 100 Hz. were used for the determination of displacement noise power between 0.1 and 50 Hz and re-sampled 20 Hz data were used for the range 0.03 to 5 Hz. The PSD subroutine described in 7.2.3.2 was used, with a basic record length of 4096 samples. The average power spectrum was determined using 25 consecutive segments with 50% overlap. Thus the spectra are representative for noise records of 8.87 min and 44.37 min length depending on whether they are based on data sampled at 100 or 20 Hz.

#### 7.2.4.3 Results of noise and signal measurements at BRNL and RUE

Fig. 7.30 shows unfiltered 5-minute broadband segments of noise recordings at BRNL and RUE taken around noon and around midnight. Fig.7.31 shows the noise power at both sites in the frequency range 0.03 to 50 Hz.

**Fig. 7.30** Unfiltered Z-component broadband records of seismic noise with identical resolution at BRNL and RUE. Upper traces: 11:50 - 11:55 UT; lower traces: 23:50 to 23:55 UT (from Bormann et al., 1997).

The comparison reveals that:

- the noise above 1 Hz at BRNL is some 15 to 25 dB higher than at RUE, both at day- and night-time;
- between 1 and 5 Hz the night-time noise is less than the day-time noise by about 10 dB at BRNL and by about 6 dB at RUE;
- below 0.5 Hz, BRNL has about the same noise power level as RUE with negligible diurnal variation at both sites;
- a range of different, spatially distributed random noise sources such as nearby traffic seem to dominate the short-period noise during day-time at both sites. This results in a rather high and "smooth" noise spectrum without any dominating spectral lines at BRNL and only a few sharp spectral lines at RUE (e.g. at  $f = 8, 10, 16$  and  $32$  Hz);
- during night-time, when the traffic noise is reduced, several sharp spectral lines become dominant for  $f > 5$  Hz at both BRNL and RUE. These are probably due to specific noise sources such as machinery rotating with constant frequency (and their lower and higher modes).

The last of these observations is clearly related to activity in the Rüdersdorfer quarry. Mining and stone crushing machinery are operating there throughout the day. Despite the generally lower noise level at RUE compared to BRNL, it is meaningful only to record at RUE low-pass filtered data ( $f_c = 5$  Hz) sampled at 20 Hz. According to Fig. 7.24 the noise power at RUE is comparable with that at station Fürstentfeldbruck (FUR), a site of intermediate quality. A better result is not achievable with a near-surface installation in the surroundings of Berlin.

**Fig. 7.31** Power spectra of seismic noise in Z-component broadband records at BRNL and RUE around noon (left) and midnight (right) (from Bormann et al., 1997).

Fig. 7.32 presents the broadband (top) and band-pass filtered (from 0.5 - 5 Hz, bottom) Z-component records at BRNL and RUE of a nearby event at approximately the same distance. In

both cases the event is not visible at BRNL but is clearly recorded at RUE with several distinct wave groups. The spectral signal-to-noise ratio (SNR) of this event is  $\leq 1$  at BRNL and varies between 3 and 30 at RUE for  $0.5 \text{ Hz} < f < 7 \text{ Hz}$ . This is a significant improvement of recording conditions. As a consequence, station BRNL was closed and its equipment permanently moved to RUE.

**Fig. 7.32** Unfiltered broadband (upper two traces) and band-pass filtered ( $f = 0.5 - 5 \text{ Hz}$ ; lower two traces) Z-component records of a near seismic event in Poland at BRNL ( $D = 214 \text{ km}$ ) and RUE ( $D = 191 \text{ km}$ ) (from Bormann et al., 1997).

#### 7.2.4.4 Results of noise and signal measurements at HAM and BSEG

Fig. 7.33 shows an example of day-time and night-time noise records at HAM and BSEG with identical resolution and Fig. 7.34 shows the related power spectra. The comparison, including that with spectra from other days and with Fig. 7.24, shows that:

- diurnal variations in seismic noise are remarkably small ( $\leq 10\text{dB}$ ) at HAM. The cause is very intense traffic and industrial activity in this busy large harbor town that does not vary much between day and night time.
- diurnal variations are significant (about 10 to 20 dB) at BSEG above 1.5 Hz but negligible below 1 Hz;
- between 0.5 and 40 Hz the noise power at BSEG is about 20 to 50 dB smaller than at HAM;
- for medium-period ocean storm microseisms (around 3 to 5 s period) the noise power is reduced by about 10 dB at BSEG;

- there is sometimes larger long-period noise at BSEG compared to HAM. This mainly non-seismic noise was significantly reduced after final installation and the level is now comparable with other good GRSN sites;
- noise conditions at BSEG above 1 Hz are only slightly inferior ( $\leq 10$  dB) to good hard-rock sites of the GRSN.

**Fig. 7.33** Five minutes of unfiltered Z-component broadband records at HAM and BSEG on July 29, 1994 at 8:00 UT in the morning (upper two traces) and after midnight (lower two traces) (from Bormann et al., 1997).

**Fig. 7.34** Noise power spectra at HAM (upper two curves) and BSEG (lower two curves) determined from Z-component records on August 1, 1994, around 9 h UT and 22 h UT, respectively (from Bormann et al., 1997).

Fig. 7.35 shows the Z-component broadband and short-period records at BSEG and HAM of a teleseismic event in Iran. The event was not recognizable at HAM but was recorded very well at BSEG. In contrast, the SNR for the P-wave onsets in long-period filtered records (Fig. 7.36) was comparable at HAM and BSEG since the P-wave wavelengths are  $> 50$  km and therefore much larger than the size of the noise-reducing velocity anomaly of the diapir structure at Bad Segeberg.

**Fig. 7.35** Z-component records of an earthquake in Iran (distance about 3800 km) at HAM and BSEG. Upper two traces: unfiltered broadband records; lower two traces: band-pass filtered with  $f = 0.5\text{--}5$  Hz (from Bormann et al., 1997).

**Fig. 7.36** Low-pass filtered ( $f_c = 0.1$  Hz) long-period 3-component records at BSEG and HAM of the Iran earthquake (from Bormann et al., 1997).

Two more examples of relatively weak ( $mb = 5$ ) earthquakes recorded at about  $76^\circ$  and  $150^\circ$  distance are shown in Fig. 7.37. Although the record traces for HAM have been reproduced at a resolution 10 times lower than the BSEG records the noise amplitudes are still much larger. The P and multiple PKP onsets (including depth phases) can be picked easily in the short-period filtered records of BSEG but not at HAM.

BSEG has now replaced HAM as a permanent GRSN station. Together with RUE, this has significantly improved the GRSN network detection and location performance for events in the northern part of Germany.

**Fig. 7.37** Short-period band-pass filtered Z-component recordings ( $f = 0.5 - 5\text{Hz}$ ) at HAM and BSEG. Upper two traces: P-wave onset of a Kurile Islands earthquake on 01.08.94 ( $D = 76.2^\circ$  to HAM,  $mb = 5.0$ ); lower two traces: PKP-wave group from an earthquake in the Tonga Islands on 30.07.94 ( $D = 150.1^\circ$  to HAM,  $mb = 5.0$ ) (from Bormann et al., 1997).

#### 7.2.4.5 Causes of spectral noise reduction at RUE and BSEG and conclusions

Bormann et al. (1997) estimated quantitatively the reduction of noise amplitudes when traveling from a medium with a low acoustic impedance to a medium with higher acoustic impedance through a sharp impedance discontinuity. Taking into account the best available values for P- and S-wave velocities as well as the densities of the various rock and sedimentary formations in the area of BSEG and RUE, it was estimated that a noise power reduction of about 18.5 dB for BSEG and of 15.6 dB for RUE would be due to the lateral impedance contrast of the anomalous geological bodies at these two sites with respect to the surrounding unconsolidated Quaternary sediments. This would explain about half of the noise power reduction observed at BSEG with respect to HAM (some 30 to 40 dB between 1 and 15 Hz). The remaining reduction of about 10 to 20 dB at BSEG can be accounted for by the distance of BSEG ( $\approx 40\text{ km}$ ) from the seismically noisy city of Hamburg.

For the noise power reduction observed at RUE with respect to BRNL (about 15 to 25 dB in the same frequency range), about 15 dB can be explained by the impedance contrast of the Rüdersdorf anticline. The change in distance to Berlin is less effective (RUE is about 20 km from the city center) because of the noise generated at a busy highway near RUE and ongoing production activity in the quarry.

Below 0.5 Hz, the effect of noise reduction due to these anomalous geological bodies is negligible because their near-surface diameter is then of the order of or smaller than the wavelength of the long-period noise. Large halokinetic, diapir or anticline structures do exist in many other parts of the world with dominating young soft sediment cover (e.g., around the Caspian Sea; west of the Zagros Mountains in Iran; in the USA). A systematic search and use of such structures (or of other anomalous local hardrock outcrops) as sites for permanent seismic recordings is recommended as a way to achieve significant short-period noise reduction. Otherwise, one has either to settle for rather bad noise conditions for near-surface installations or go for expensive borehole installations (see 7.4.5).

### **7.3 Data transmission by radio-link and RF survey**

(A. Trnkoczy, 2002; for an update on modern communication systems used in seismology see the new IS 8.2 of 2013)

#### **7.3.1 Introduction**

Radio links are often used for data transmission in a seismic network. Radio links offer seismic data transmission in real time, are continuous, independent, often robust to damaging earthquakes, and usually involve a reasonable cost.

However, experience shows that the most frequent technical problems with radio frequency (RF) telemetry networks originate in the RF links themselves. This is often the result of a non-optimally designed RF system. Many seismic networks in the world experience unreliable and noisy data transmission. There are even reports of some complete failures. This Chapter gives some general advice on how to design a seismic telemetry system, covering VHF (usually 160 - 200 MHz for seismology) and UHF (usually around 450 MHz for seismology) frequency band FM modulated links, as well as spread spectrum (SS; around 900 MHz or 2.4 GHz) RF data transmission and satellite . The need for a professional RF survey will be explained.

The UHF and VHF frequency bands are still the most frequently used. Spread spectrum and satellite links are becoming more popular in seismology.

#### **7.3.2 Types of RF data transmission used in seismology**

Most of today's RF telemetry seismic networks use the VHF or UHF frequency band. Both bands can be used for frequency modulated (FM) analog signal transmission or digital data transmission with a variety of modulation schemes. Both usually use standard 3.5 kHz bandwidth "voice" channels. It is much easier to obtain permission for these than for special channels with a higher bandwidth. Direct connection distances of up to 150 km (100 miles) are possible with less than one Watt RF power transmitters, if topography permits.

Unfortunately, the VHF band is almost completely occupied in most countries. It is therefore very difficult or even impossible to get permission to use this band. The band is also more susceptible to interference from other RF users and therefore is rarely used for new seismic networks.

Until very recently, the UHF band has been the most popular. But it is now becoming difficult to obtain permission for new frequencies within this band in many countries.

Spread spectrum RF telemetry is a new and increasingly popular alternative in seismology. These links operate at frequencies around 900 MHz or 2,4 GHz. Spread spectrum RF links do not use a single carrier frequency but instead use the entire frequency band dedicated for such links. Many users use the same frequency band so the corresponding transmitter and receiver must identify each other to discriminate from other users using special codes.

The practical advantages of spread spectrum links are that often no permission is needed for their operation and that they are very robust against RF interference (the technology was first developed for defense purposes for just this reason). There are limitations, however, because the maximum RF power of transmitters is defined by national regulations, varies greatly, and dictates the maximum practical connection distance between a transmitter and a receiver. This may impose severe limitations on the wider use of spread spectrum links for seismology. In Western European countries where the limit is 100 mW, connections are only possible up to 20 to 30 km. Direct connection distances around 100 km can be achieved using stronger transmitters (up to 4W) only in the countries that allow them.

Satellite links are becoming more popular in seismometry and undoubtedly represent the future for seismic data transmission. Costs are still a hindrance to the widespread implementation of this technology but these will surely come down.

Most of the commercially available satellite links are of the high throughput type. Usually they are purchased as 110 kHz bands in the GHz frequency range (e.g., Ku-band: 11 to 14 GHz). Frequently, the smallest available bandwidth (and consequently the baud rate) is much higher than usually required for a seismic station or even for a small seismic network. This makes satellite links relatively expensive for small networks. Prices for one 110 kHz band are currently around several hundred dollars per month (1998).

If the size of the network and the total bandwidth required is equal to or slightly smaller than any multiple of the available bandwidth increments, the cost of satellite data transmission may be more acceptable. This is easier to achieve in large national or regional seismic networks. The number of seismic data channels that can be transmitted in a 110 kHz frequency band depends on several parameters: the sampling rate; the number of bits per data sample (dynamic range); whether single direction (simplex) or bi-directional (duplex) links are used; the overhead bits required for error detection, forward error correction (FEC), and link management.

One of the important issues which varies from country to country relates to the central satellite recording site (the hub). In some countries, where the communication market is open, a seismic network owner may have its own 'private' hub directly at the central recording site. The cost of equipment for such a local hub varies from \$80,000 to about \$200,000 (in the year 2001). In countries with a more restricted communications market only a shared hub owned by a communications company may be available. In this case, not only is the cost of satellite communications higher but there will be additional costs for the communication links from the shared hub to the seismological central recording site. These usually use leased lines and the costs can be significant, particularly if the distance involved is large. Cost analysis of different satellite systems is complex and the prices vary significantly from country to country. A very careful cost analysis is recommended before making any final decision about satellite links.

A practical problem with satellite links is the relatively high power consumption of the equipment installed at a seismic station. In most cases, we must consider at least 50W power consumption for the data transmission equipment at each site. This significantly exceeds the power consumption of RF equipment traditionally used in seismology, including spread spectrum transmitters. It creates the need for large arrays of solar panels at stations without mains power and for bigger back-up batteries for a given station autonomy.

Nonetheless, the costs of satellite communications are constantly decreasing thanks to increasing liberalization in the communications market which will encourage the use of satellite links. No other communication system has the potential of satellite links for high reliability at the most remote and distant seismic stations.

### **7.3.3 The need for a professional radio frequency (RF) survey**

The design of VHF, UHF or spread spectrum RF telemetry links in a seismic network is a specialized professional technical matter. Practice shows that guesswork and an approach based on "common sense" usually lead to problems or even complete failure of a project. The following misunderstandings and oversimplifications are commonly encountered:

- the amount of data that must be transmitted in seismology is often underestimated. Seismology requires a much larger data flow (baud rate) than most other geophysical disciplines, for example several orders of magnitude more than meteorology;
- the required reliability for successful data transmission in seismology is also frequently underestimated. Missing data due to interruptions on the links, excessive noise, spikes, and data errors are particularly destructive for networks operating in triggered mode and/or having any kind of automatic processing. With old paper seismograms and analog technology, spikes, glitches, interruptions and other 'imperfections' are relatively easily "filtered out" by the seismologist's pattern recognition ability during the analysis. However, the same errors, if too frequent, can make the results of an automatic computer triggering and/or analysis totally unacceptable;
- a false comparison with voice RF channels is made frequently. People try to verify a seismological RF link between two points using walkie-talkies. If they can communicate, they expect that transmission of seismic data will also be successful. Note that voice channels allow a much lower signal-to-noise ratio while still being fully functional because human speech is highly redundant. Also, the RF equipment parameters in walkie-talkies and in seismic telemetry are very different, making such "testing" of RF links meaningless.
- another wide-spread belief is that the "line of sight" between transmitter and receiver is a sufficient guarantee for a reliable RF link. This may or may not be true. It is only certain for very short links up to about 5 km length with absolutely no obstructions between the transmitter and the receiver (such links may occur in some small local seismic networks). Fading, i.e., the variation of the intensity or phase of an RF signal due to changes in the characteristics of the RF signal propagation path with time, becomes a major consideration on longer links. The real issues in link reliability

calculations are the equipment's gains and losses, RF signal attenuation based on Fresnel ellipsoid obstruction, and the required fading margin. The resultant reliability of the link can then be expressed as a time availability (or probability of failure or time unavailability) as a percentage of time in the worst month of the year (or per year). During 'time unavailability', the signal-to-noise ratio at the output of the receiver is lower than required, or the bit error rate (BER) of digital data transmission link is higher than required. Many parameters are involved in the RF path analysis including transmitter power, frequency of operation, the various losses and gains from the transmitter outward through the medium, receiver antenna system to the input of the far end receiver and its characteristics. In link attenuation calculation, the curvature of the Earth, the regional gradient of air refractivity, the type of the link regarding topography, potential-wave diffraction and/or reflections, time dispersions of the RF carrier with digital links, processing gain and background noise level with spread spectrum links, etc. all play an important role.

We strongly recommend having a professional RF survey during the seismic network planning procedure. IS 7.1 provides the information on what preparation is needed if an RF survey is purchased as a service along with the seismic equipment.

### **7.3.4 Benefits of a professional RF survey**

The benefits of a professional RF survey are:

- it ensures that the links will actually provide the desired reliability, which has to be decided beforehand. During the RF survey, the design parameters of the links in a network are varied until the probability of an outage in the worst month of a year drops below the desired value. This may require additional investment in equipment, but it will prevent unreliable operation or may save some money by loosening the requirements where appropriate;
- it guarantees the minimum number of RF repeaters in a network. This results in a direct benefit to the user in having less equipment, fewer spare parts, and in cheaper and easier maintenance. There will also be lower instrumental noise in the recorded signals for FM analog networks and a better BER performance for digital networks. Note that in most designs for analog FM telemetry, every additional repeater degrades data quality to some extent and always decreases the network reliability;
- It will determine the minimum number of licensed frequencies required in a network without sacrificing data transmission reliability. Note that the required number of different carrier frequencies in VHF and UHF telemetry can be significantly smaller than the total number of the links in the network. This prevents unnecessary pollution of RF space in the country. Use of fewer frequencies also benefits the user since they are easier to obtain and fewer different RF spare parts are required;
- the robustness of the entire seismic network to lightning threat is significantly increased by a proper RF layout, for example, one should always avoid repeaters which relay data from many seismic stations because any technical failure of the repeater will result in severe data loss;
- reduced power consumption can be achieved by calculating the minimum sufficient RF output of the transmitters. This results in less pollution of RF space in the country. The user also benefits from lower power consumption at remote stations;

- minimizing the heights of antenna masts and the minimum gains of the antennae has potential for cost saving.

### 7.3.5 Radio-frequency (RF) survey procedure

An RF survey usually considers the RF equipment to be used, a topographical profile from each transmitter site (remote seismic station) to each receiver site (central recording site or repeater), local RF path conditions, and the desired reliability of the link. It is based on decades of experience of transmission statistics from all over the world and computer modeling using specialized software. Field RF measurements are rarely performed because they are expensive and time-consuming and they are often less reliable than calculations. RF transmission conditions vary with time (diurnal, seasonal, weather dependent), vary unpredictably and within climatic zones. Theoretical calculations include the full statistics of these variations whereas practical one-time measurements suffer from unpredictable variations in fading. However, even if no measurements are planned, a communications expert still has to visit all potential seismic sites during the site selection procedures to assess local topography and to check for the existence of potential RF obstacles which may not be evident from topographic maps.

If the RF link calculation based on a given set of input parameters does not give the desired reliability, some of the input parameters must be changed. We can change topographical profile by either repositioning stations or by introducing a new RF repeater. We can change the antenna type and/or increase their gain. We can increase antenna mast height or increase transmitter output power (seldom effective) or we can change the RF equipment completely (significantly more powerful transmitters and/or more sensitive receivers).

Topographic profiles are usually taken from 1:50.000 scale topographical maps. In most cases, many more profiles than stations available in the network are taken and links calculated before we determine the final RF layout of a network. A great deal of this work can be done before fieldwork starts, but profiling is always needed during the fieldwork.

The result of an RF link calculation is shown in Fig. 7.38 with input parameters on the left and output parameters on the right. The figure intentionally shows an example where there is a "direct line of sight", but the profile doesn't guarantee acceptable link operation. Note the curved path of the first Fresnel ellipsoid where the RF energy actually travels from the transmitter to the receiver. This curvature is mostly due to the regional gradient of air refractivity. In the example, this ellipsoid hits the mountain ridge and causes a significant loss of energy or possibly link failure.

For analog VHF or UHF telemetry it is usual to regard a time availability of about 99.95% (equivalent to about 15 minutes of outage of each link per month) in the worst month as being marginally acceptable and 99.99% as good. If we use an RF repeater between the seismic station and central recording site, we have to increase the required reliability of individual sections to give the required reliability for the entire link.

In digital data transmission, the bit error rate (BER) is used as a measure of data link reliability. BER strongly depends not only on physical reliability of the RF link but also on error detection and error correction methods used in the RF equipment (modems). For example, one-directional (simplex) links are generally far less reliable than bi-directional

(duplex) links, even if the RF links themselves are of the same quality in terms of RF signal to noise. This is because duplex links allow repeated transmission of corrupted data blocks until they are received without error whereas simplex links result in corrupted data, unless forward error correction (FEC) methods are used. Due to the complexity of the problem, a precise targeting of desired BER is usually beyond the scope of seismic network projects.

**Fig. 7.38** Result of an RF link calculation with input parameters on the left and output parameters on the right.

Something similar is the case for spread spectrum links where another factor complicates the situation. Spread spectrum receivers incorporate so-called "processing gain". These receivers are capable of resolving very weak RF signals, which may even be a few dB below the RF

noise at the receiver site. However, the problem is that the amplitude of the RF noise at the receiver site is generally unknown. Note that every new spread spectrum transmitter increases the background noise in the band of operation of the spread spectrum system and since this band is open to the public, it is difficult to predict its actual noise. Consequently we will not know exactly the sensitivity of a receiver, resulting in a less reliable estimate of the link availability.

Specialized spread spectrum measuring equipment is extremely expensive. The algorithms which are used to resolve the sub-noise level RF signals in the receivers also present a problem. They are mostly proprietary and therefore not generally accessible. Both facts significantly reduce the practicality of measurements of the reliability of spread spectrum links for seismological purposes.

Fortunately, some spread spectrum equipment manufacturers provide special software which allows easy but approximate link reliability measurements for the transmitters and receivers to be used in the seismic system. Taking into account a safety margin due to temporal variation of RF transmission conditions, one can successfully use these measurements for an approximate estimate of link quality. However, it is difficult to relate these proprietary 'reliability scales' to standard parameters like probability of link outage or BER. Nevertheless, classical RF signal attenuation calculations still give valuable information about RF energy propagation over a given topographic profile. These results, combined with measurements using manufacturer's proprietary 'reliability scales' and practical experience, suffice in almost all seismometric projects.

The cost of a professional RF survey is generally around a few percent of the total investment in a new seismological network. Practice shows that its benefits are well worth the investment. An RF survey is a major step toward the reliable operation of any future telemetry seismic network.

### **7.3.6 The problem of radio-frequency interference**

While spread spectrum links are fairly robust, radio-frequency interference between a VHF or UHF seismological system and other RF users is quite a common and difficult problem in many developing countries. In some countries, the lack of discipline in RF space causes unforeseen interference. In others, insufficient maintenance of high-power communication equipment results in strong radiation from the side-lobes of powerful transmitters that may also interfere with seismological links. Army facilities, particularly if they operate outside civil law, especially some types of radars, frequently interfere with seismological links. The risk of interference is very high if seismic stations are installed at sites which are also used for other high power RF communication equipment (see IS 7.2). Extensive use of walkie-talkies can also cause problems.

In some developing countries, the use of RF spectrum analyzers, which can frequently reveal the origin of interfering signals, is prohibited for security reasons, particularly for foreigners. In any case, interfering RF sources may appear only very intermittently and so are difficult to detect.

Note that RF interference problems due to indiscipline in RF space are generally beyond the control of a seismic equipment manufacturer and/or foreign RF survey provider. They can

only be solved, or at least mitigated, by involving local RF communication experts during the very early phases of network planning. These people are familiar with the real RF conditions in the country and can provide better advice than any foreign expert. If a new seismic network experiences interference problems, only very tedious and time consuming trial-and-error procedures (swapping frequencies of the links or even VHF/UHF bands, changing antenna orientation and polarization, or even re-positioning of stations or repeaters) may help. However, the results are unpredictable. One should also be aware that the allocation of frequencies may change in future and disturbances remedied today may reoccur later.

## **7.4 Seismic station site preparation, instrument installation and shielding**

### **7.4.1 Introduction and general requirements (A. Trnkoczy; version 2002)**

When installing a seismometer inside a building, vault, or cave, the first task is to mark the orientation of the sensor on the floor. This is best done with a geodetic gyroscope although a magnetic compass will often suffice. The magnetic declination must be taken into account. A compass may be deflected, showing a false reading, when inside a building so the direction should be taken outside and transferred to the site of installation. A laser pointer may be useful for this purpose. When the magnetic declination is unknown or unpredictable (such as in high latitudes or volcanic areas), the orientation can be determined with a sun compass. Special requirements and tools for sensor orientation in boreholes are dealt with in 7.4.6.2.

To isolate the seismometer from stray electric currents, small glass or perspex plates should be cemented to the ground under its feet. The seismometer can then be installed and tested. Broadband seismometers should be wrapped with a thick layer of thermally insulating material. The exact type of material does not seem to matter; alternate layers of fibrous material and heat-reflecting blankets are probably the most effective. The edges of the blankets should be taped to the floor around the seismometer. Further information on suitable and proven thermal insulation for broadband seismometers, including illustrations, can be found in 7.4.2.1, 7.4.4.2 and 5.5.3. One has to be aware that electronic seismometers generate heat and so may induce convection in any open space inside the insulation. It is therefore important that the insulation fits the seismometer tightly.

For the permanent installation of broadband seismometers under unfavorable environmental conditions, they should be enclosed in a hermetic container. A problem with such containers (as with all seismometer housings) is that they cause tilt noise when they are deformed by barometric pressure. Essentially three precautions are possible: either the base-plate is carefully cemented to the floor, or it is made so massive that its deformation is negligible, or a "warp-free" design is used, as described by Holcomb and Hutt (1992) for the STS1 seismometer (see DS 5.1).

To prevent or reduce corrosion in humid climates, desiccant (silica gel) should be placed inside the container, including inside the vacuum bell, of an STS1 seismometer. Broadband seismometers may also require some magnetic shielding (see 5.5.4).

Civil engineering work at remote seismic stations should ensure that modern seismic instruments can be used to their fullest potential by sheltering them in an optimal working

environment. Today's high dynamic range, high linearity seismic equipment is of such quality and sensitivity that seismic noise conditions at the site and the environment of the sensors have become much more important than in the past. Apart from site selection itself, the design of seismic shelters is the determining factor in the quality of seismic data acquisition.

Seismic vaults are currently the most common for new seismic stations (see 4.2). They are the least expensive but suffer more from seismic noise because of their near-surface installation. Alternatives include seismic installations in abandoned mines, in specially constructed tunnels (see 7.4.3) and in boreholes (see 7.4.5 and 7.4.6). These have the advantage of high temperature stability and significantly reduced surface and tilt noise because of the significant overburden. The low tilt noise is of particular importance for long-period and broadband seismometers because of their high tilt and temperature sensitivity (see 7.4.4, 5.3.3 and 5.3.5). A variety of factors must be considered before the optimal technical and financial solution for a seismic installation is found. These include the type of monitoring or research to be carried out, the kind of equipment to be installed, existing geological and climatic conditions, already existing potentially suitable structures and sites, available construction materials or alternative technical solutions, accessibility of and available infrastructure/power supply at the station.

Various solutions can be employed with equal success. Much depends on potential future upgrades of the instrumentation and site, what working conditions are desired for maintenance and service personnel, and, of course, on the funds available. Because of these diverse considerations, no firm design and civil engineering drawings are provided in this document. Instead, the general requirements that must be satisfied are described in detail so that, e.g., in the case of seismic vaults, any qualified civil engineer can design the shelter for optimal performance, taking into consideration local conditions in a given country and at a specific site.

## **7.4.2 Vault-type seismic stations (A. Trnkoczy; version 2002)**

This section describes the general conditions to be considered when constructing seismic vaults. A vault for seismic data acquisition and transmission equipment should satisfy the following general requirements:

- provide adequate environmental conditions for the equipment;
- ensure the proper mechanical contact of seismic sensors with bedrock;
- prevent seismic interaction between the seismic shelter and the surrounding ground;
- mitigate seismic noise generated by wind, people, animals, and by potential noise sources within the vault;
- ensure a suitable electric ground for sensitive electronic equipment;
- provide sufficient space for easy access and maintenance of the instruments.

These requirements will be discussed in detail below. A design example of a seismic vault for a three-component short-period (SP) station together with its upgrade for broadband (BB) and potentially very broadband (VBB) seismic sensors will be given, complemented by some technical hints at the end of this section. Other examples of vault-type seismic shelters are given in 7.4.4.3. Detailed installation guidelines for BB and VBB stations can be found in Uhrhammer et al. (1998). Alternative vault designs of typical 'classic' seismometer vaults are given in Figures 4.5b-e of the old MSOP (Willmore, 1979; also accessible on the IASPEI website <http://www.iaspei.org/projects/NMSOP.html> via the link Manual of Seismological

Observatory Practice (1979 Edition)). Some recent complementary comments have been added by the Editor in the inserted box below.

### **Complementary comments on seismometer installations in vaults and on piers (2011)**

Several NMSOP-1 users asked to specify somewhat more in this section how to “decouple” best the place or pier on which a seismometer is installed in a vault or in a building from ambient and human disturbances. The editor asked two experts. Their answers see below:

#### **Amadej Trnkoczy on 15.06.2011**

Regarding the vault design my opinion has always been the same: dig the vault until you reach a good bedrock, then put as little as possible fine concrete on it to make a flat surface big enough to put a seismometer or seismometers on it. Build around the vault as small and as light as possible 'housing', the best is none. Just a firm (strong wind!), water tight cover over the vault and that is it. In this case there is no structure/soil or structure/seismic pier interaction possible since there is practically no 'structure'. The problem is solved.

Generally modern seismic instruments are so sensitive that there should be no housing for people to live or work close to them. To my opinion there is no way to decouple a seismic pier from human activity so close to it. Also such housings may cause problem during windy periods.

In old times, when sensors were much less sensitive, this was allegedly possible using several different methods (like "mechanical dampers", or separate foundation for the housing and for the pier, etc). I would not recommend such approaches for regular seismic stations of a seismic network today.

#### **Thomas Forbriger on 27.06.2011**

“Decoupling” is probably meant to avoid noise on the pier caused by forces exerted on the external surface of the vault. Most effective decoupling should always be achieved by underground installations in solid rock and good coupling of the pier to bedrock. Better decoupling as provided by overburden competent rock probably cannot be achieved by any other measures.

Explicit decoupling from the housing in above-surface installations may be an issue in sedimentary settings (loose soil). In such cases you should avoid mechanical coupling of the pier to the walls of the above-surface building. There should always be a gap in between with the pier being only coupled to the ground (if possible on bedrock). This will however not avoid noise coupled to the ground surface outside the building which can be significant for long-period observations in above-surface installations.

Better focus on good coupling of the pier to bedrock.

### **7.4.2.1 Controlling environmental conditions**

Adequate shelter for seismic equipment should:

- prevent large temperature fluctuations in the equipment due to day/night temperature differences or because of weather changes;
- prevent large temperature fluctuations in the construction elements of the vault, resulting in seismometer tilt;
- ensure adequate lightning protection;
- mitigate electromagnetic interference (EMI);
- prevent water, dust and dirt from entering the shelter;
- prevent small animals from entering the shelter.

At very low seismic frequencies and in VBB seismometers, air pressure changes also influence seismometer output. Special installation measures and processing methods can be used to minimize the effect of air pressure. However this issue will not be treated here. For more information see Beauduin et al. (1996).

### ***Mitigating temperature changes***

In general, seismic equipment can operate in quite a broad temperature range. Most of the equipment on the market today is specified to function properly between  $-20$  and  $+50$  degrees Celcius. However, this is the operating temperature range – that is, guaranteeing only that the equipment functions at a given constant temperature within these limits.

Temperature changes with time, particularly diurnal changes, are far more important than the high or low average temperature itself. Many broadband seismometers require mass centering if the temperature "slips" more than a few degrees Celcius, although their operating range is much wider. Even small temperature changes can cause problems with mechanical and electronic drifts which may seriously deteriorate the quality of seismic data at very low frequencies. Unfortunately, the practical sensitivity of the equipment to temperature gradients is rarely provided by manufacturers. Very broadband (VBB) seismometers require extremely stable temperature conditions which are sometimes very difficult or impossible to assure in a vault-type shelter. VBB sensors usually require special installations (see Uhrhammer et al., 1998). Short-period (SP) seismometers, particularly passive ones, and accelerometers are much less sensitive to temperature changes.

In general, thermal drifts should be kept acceptably small by thermal insulation of the vault. However, the requirements differ significantly. Maximum  $\pm 5$  deg C short-term temperature changes can be considered a target for passive SP seismometers and force-feedback active accelerometers. To fully exploit the low-frequency characteristics of a typical 30-sec period BB seismometer, the temperature must be kept constant within less than one degree C. To fully exploit a several-hundred-seconds period VBB sensors only a few tens of millidegrees C per month are recommended.

Data loggers and digitizers can tolerate less stable temperatures, i.e., on average, the temperature change would be ten times greater than on a BB seismometer for the same change in output voltage. The best digitisers, for example, change their output voltage less than  $\pm 3$  counts in room temperature conditions. If daily temperature changes are less than 1 deg C, their output voltage changes less than  $\pm 1$  count (Quanterra, 1994).

Some elements such as some computer disk drives, diskette drives, and certain time-keeping equipment, may require narrower operating temperature tolerances. The most effective way to assure stable temperature conditions is an underground vault that is well insulated (see Fig. 7.39). Underground installations are also the best for a number of other reasons.

Thermal insulation of active seismic sensors is done in two places. First, the interior of the vault is insulated from external temperatures, and second, the sensors themselves are insulated from residual temperature changes in the vault. In the most critical installations, the seismic pier itself is insulated along with the sensors.

**Fig. 7.39** Example of a vault for a short-period three-component seismic station made of a large-diameter metal pipe with thin concrete walls.

Underground vaults are usually insulated with a tight thermal cover made of styrofoam, foam rubber, polyisocyanuratic foam, or other similar, non-hygroscopic insulation material (Fig. 7.39, Figs. 7.41 and 7.42). Such materials are usually used in civil engineering for the thermal insulation of buildings. They come in various thicknesses, often with aluminum foil on one or both sides. This aluminum layer prevents heat exchange by blocking heat transfer through radiation. Thinner sheets can be glued together to make thicker ones. Casein-based glues are appropriate for styrofoam and expanding polyurethane resin is used to glue polyisocyanuratic foam sheets.

In continental climates, a 20 cm (8") layer is considered adequate but in extreme desert climates, up to 30 cm (12") of styrofoam is recommended. In equatorial climates a 10 cm (4") layer is considered sufficient.

There are two thermal cover design issues that are particularly important. Special care must be taken to assure a tight contact between the vault's walls and the thermal cover. If it is not tight, heat transfer due to convection through the gaps can easily be larger than the heat transfer through the thermal cover by conduction. This can undo the insulating effects of the cover. One way to achieve a tight thermal cover is shown in Fig. 7.43. A "rope" is tightly pressed into the gaps between the vault's walls and the thermal cover as well into the wedge-like gap between the cover halves seen in Fig. 7.41. This "rope" can be made of insulating fibers and is usually used for industrial hot water pipe insulation. It is available in different sizes and is inexpensive.

The cover should be placed at or below the depth at which the ground heats up during the day – not on the top of the vault. In desert areas, surface ground temperatures can exceed 80 deg C. At 30 cm (12") depth, temperatures of 50 deg C are not unusual. In such conditions, the thermal cover must be placed 40 - 50 cm (16" - 20") below ground level. A thermal cover of any thickness at the top of the vault, particularly if the vault's rim stands significantly above the surface, has almost no effect.

**Fig. 7.40** Interior of a seismic vault made of welded metal sheets. The vault is big enough to accept weak- and strong-motion instrumentation together with data acquisition and transmission equipment.

**Fig. 7.41** Thermal cover of a seismic vault in two pieces made of thick styrofoam. The gaps between the cover and the vault walls and between both pieces must be tightly sealed.

**Fig. 7.42** Installing thermal cover in a seismic vault. In climates with large diurnal temperature changes the cover should be positioned lower in the vault where external ground temperature does not change significantly.

If vaults are used for BB or even VBB stations (see Wielandt, 1990), it is advisable to make a second inner thermal cover just above the sensor but below the floor where all other equipment is installed (see Fig. 7.44). Since most maintenance work relates to batteries, data recording, and data transmitting equipment, the thermal- and mechanical-sensitive BB/VBB sensors are not disturbed at all during service visits.

**Fig. 7.43** Detail of making a thermal cover effective by filling up the gaps between the cover and vault walls with insulation material and making the vault tight against dust, dirt, and rain during windy periods with a fabric cover.

**Fig. 7.44** Example of a BB or VBB seismic vault with a separate compartment for sensors and double thermal cover. Usually, the sensor itself is additionally isolated (see. Fig. 7.50). A thermal isolation box is usually put around the sensors to additionally insulate them.

Thermal insulation of the seismic pier itself, together with the seismometer, is the best method of insulation (Fig. 7.45). This method keeps the heat transfer between seismometer and vault interior as low as possible, while at the same time assuring good thermal contact with the thermally very-stable ground. Thus, the thermal inertia of the system is very large, limiting the rate of temperature changes to a minimum.

**Fig. 7.45** Thermal isolation of a VBB sensor and surrounding seismic pier and mechanical separation of the pier from the vault walls for the most demanding applications.

### ***Thermal tilt mitigation***

Special measures are required to prevent thermal deformation and tilt of the seismic pier in a vault to allow the study of extremely low frequency signals with VBB seismometers. Modern VBB sensors, the horizontal components in particular, can detect tilts of a few nanoradians. A human hair placed under the corner of a level football field or an air pressure difference of only 0.1 mbar over a distance of several km would cause such a tilt. According to Wielandt (see section 5.3.3) a tilt of about  $10^{-9}$  rad would result in a noise ground acceleration amplitude of  $10^{-9}$  g in the horizontal components but only of  $10^{-11}$  g in the vertical one.

Homogeneity of the seismic pier and surrounding soil, as well as civil engineering details of vault design are very important. Uhrhammer et al. (1998) recommend the physical separation of the seismometer pier and the vault walls (see Figs. 7.44 and 7.45). This separation assures that minute changes in the dimensions of the vault walls due to temperature change do not tilt the seismic pier. However, since such seismic vaults are not constructed "in one piece," one has to be particularly careful that the contact between the pier and vault walls is still watertight.

The seismic pier should be made of homogenous material and neither it nor the walls of the vault should use any steel reinforcement. Steel and concrete have different temperature expansion coefficients which cause stress and unwanted minute deformation of the structure of the vault if the temperature changes. Steel is unnecessary anyhow because structural strength is practically never an issue except in the very deepest of vaults. Sand aggregates used for concrete should be homogenous, fine-grain, and of uniform size rather than of varying size as in the usual concrete mixture. Uhrhammer et al. (1998) recommend sieved sand with 50% Portland cement. After the pier is poured, the concrete must be vibrated to remove any trapped air.

### ***Lightning protection***

Lightning causes most of the damage to seismic equipment around the world and lightning protection is probably the most important factor in preventing station failure. We know of several seismic networks that lost half or more of their equipment less than two years after installation because of inadequate lightning protection. Of course a direct hit by lightning will cause equipment damage despite the best protection. Fortunately, this rarely happens. Most lightning-related damage is caused by induction surges in cables, even when the source is some distance from the station.

Climatic and topographic conditions at a site vary greatly and determine the degree to which one should protect the system from lightning. Tropical countries and stations on top of mountains are the most vulnerable and therefore require the most lightning protection measures.

Lightning protection includes the following measures:

- proper cabling that minimizes voltage induction during lightning;
- proper use of special electronic devices to protect all cables entering the seismic vault from voltage surges;
- a good grounding system since no practical lightning protection measure works without grounding;
- enclose the equipment in a "Faraday cage" either by making a metal shielded seismic vault or a loose mesh of ground metal strips around the vault. This creates an equipotential electric field around the equipment, thus decreasing voltage drops on equipment and cables during lightning strikes.

If any one of these measures is not undertaken, the others become largely ineffective.

The best lightning protection is a metal seismic vault. The exterior of the vault should not be painted so that good electrical contact can be made with the surrounding soil, thereby lowering impedance. If the main cover or any other part of the vault is metal, it should be connected to the vault's walls using a thick flexible strained wire.

In any event it is necessary to protect all cables entering the seismic vault. Many high quality seismic instruments already have internal lightning protection circuitry, but these measures are sometimes not enough for high lightning threat regions. Lightning protection may include gas-discharge elements, transient voltage suppressors (transorbs), voltage dependant resistors, and similar protection components.

The lightning protection equipment of the cables must be installed at the point where they enter the vault. It must be grounded at the same point with a thick copper wire or strip that is as short as possible. The unprotected length of any cable within the vault must be kept to an absolute minimum.

All cables entering the vault must be protected. Voltage surges usually occur in all cables, and leaving a single long cable unprotected is virtually the same as leaving all the cables unprotected.

All metal equipment boxes should be grounded with a thick copper grounding wire or strip (> 25 mm<sup>2</sup> cross-section) to the same point where the lightning protection equipment of incoming cables is grounded. Use a tree-shaped scheme for grounding wires. All these wires

should be as short as possible and without sharp turns. All the cables in a vault should be kept to a minimum length. No superfluous cables or even coiled lengths of excess cable are acceptable. These are true lightning catchers.

Telephone and power companies usually install lightning protection equipment for their lines. This should be required of them when arranging these services. Manufacturers of seismic equipment can also provide and install such equipment if asked.

Note that there is never a 100% safe lightning protection system. However, for high lightning risk regions and for expensive and delicate seismic equipment, long years of practice show that investing in an effective lightning-protection system pays off in the long run.

### ***Electro-Magnetic Interference protection***

The problem of electro-magnetic interference (EMI) is not normally a very important issue because seismic stations are generally situated in remote rural locations. However, in such regions the main power lines can frequently be of low quality. We recommend using mains power voltage stabilizing equipment in such cases. This equipment usually incorporates EMI filters and voltage surge protection, which further protects seismic equipment from failures and EMI-generated noise. In general, metal seismic vaults protect equipment from EMI very effectively.

Some passive seismometers with moving magnets and separate components generate EMI during mass motion. Since this may influence surrounding sensors, you should not install such seismometers too close together. A minimum distance of 0.5 m (1.5 feet) is recommended. A simple test can assure you that cross talk is insignificant. Disconnect and un-damp one component, move the seismometer mass by shaking it slightly and measure the output of both the other components. There should be no cross-talk.

In addition, seismometers should not be placed too close to the metal walls of a vault. This minimises potential changes in the static magnetic field, which may slightly influence the generator constant of some seismometers.

Data recording equipment with mains transformers should not be installed next to, or on the same pier as sensors. The transformer may cause noise in the seismometer signals either through its magnetic field or due to direct mechanical vibrations at 50 or 60 Hz. The same is true for magnetic voltage stabilizers, if used at the site. Place such equipment in a metal housing for additional magnetic shielding and install it on the wall of the vault.

### ***Water protection***

Water entering seismic vaults is probably the second most common cause of station failure. The most effective way to prevent water damage is vault drainage (Fig. 7.46). Use a hard plastic tube of about 3 cm (1") diameter, such as used for water pipelines. The drainage pipe must be continuous and have at least a 3% gradient, particularly in regions where the ground freezes during the winter. If drainage is impossible, as is often the case for deep vaults, water tightness of the vault is of the utmost importance. Note that a high ground water level and porous concrete vault walls more or less guarantee water intrusion.

Water tightness is easy to achieve if the walls of the vault are made of metal welded from plain or corrugated iron sheets or from large-diameter metal tubes, providing the welds are of

good quality. If the vault is made of concrete and has no water drainage, the concrete should be of a very good, uniform quality. Water-resistant chemicals should be added to the mix to help keep it water-tight. The concrete must be vibrated during construction to assure homogeneity of the walls.

**Fig. 7.46** Water drainage pipe and vault trench around the seismic pier.

The bottom of the seismic vault - the seismic pier - is always made of concrete. Once again, use good quality, uniform-aggregate concrete with water-resistant additives. The bottom should have a water drainage ditch (see Figs. 7.39 and 7.46) around the flat central pier on which the sensors are installed. For vaults with external water drainage, the ditch should be at least 5 cm (2") deep and 10 cm (4") wide. For the vaults without drainage, this ditch should be larger (at least 15-cm by 15-cm or 6"x 6") so it can collect more water.

Making the joint between the vault walls and floor requires special care. Use asphalt to seal any cracks by heating the concrete with a hot-air fan and then pouring hot asphalt into them. The cables entering the vault also require special care. They are normally installed in a plastic or metal tube that should fit snugly into the appropriate hole in the vault wall. Use silicon rubber or asphalt to seal any gaps.

In vaults designed for VBB seismometers whose seismic pier is mechanically separated from the walls, water tightness represents a special challenge. Once again use soft asphalt to make the gap between the walls and the pier watertight.

The upper rim of the vault must be at least 30 cm (1 foot) above the ground. At sites where a lot of snow is expected, this should be higher, up to 60 cm (2 feet). Slush is particularly troublesome with regard to keeping vaults watertight. Where possible, the surrounding terrain should descend radially from the top of the vault.

One practical measure is to create a small "overhang" at the top edge of the vault (see Fig. 7.43). This ledge should be about 5 cm (2") out from the vault wall. A thick, watertight fabric cover can be hooked over this metal edging. The cover is pulled tight to the vault by rope and prevents water from entering the vault during windy, rainy periods. It also protects against dust and dirt and provides some additional thermal insulation.

To minimize the danger of equipment flooding, install all equipment, apart from the sensors, on the wall of the vault or on a raised platform.

### ***Protection from small animals***

At first glance the issue of small animals may seem amusing. However, animals frequently use seismic vaults as dwellings. We have seen some very strange "seismic" records caused by ants, grasshoppers, lizards, and mice. Worse, such animals can cause severe damage to cables and other plastic parts of the equipment.

Tight metal (particularly effective), fabric or thermal vault covers usually prevent animals from entering the vault from above. Plastic tubes for cables and drainage should be protected by metal mesh. Placing metal, wool or glass shards in the free space in these tubes also helps. Insecticides can be used to drive away ants and other insects.

In extreme circumstances, animals may be deterred from chewing cables and other equipment by applying paints developed to prevent animal damage to trees.

### **7.4.2.2 Contact with bedrock**

Good contact between seismic sensors and bedrock is a basic requirement. Soil and/or weathered rock layers between the sensor and the bedrock will modify seismic amplitudes and waveforms.

The depth of bedrock and the degree of weathering of layers beneath the surface can be determined by shallow seismic profiling of the site, by drilling (most often too expensive), or by actually digging the vault. Only rarely will a surface geological survey provide enough information about the required depth of the seismic vault (except where the bedrock is clearly outcropping).

If you choose not to carry out a shallow seismic profile, then expect surprises. You will need to dig until you reach bedrock, and that can sometimes be very deep; a vault may have to be repositioned and re-dug if weathered bedrock is extremely deep. These risks make the cost of shallow profiling a wise investment.

A definition of "good" bedrock is necessary when digging vaults without a seismic profile. Unfortunately, the definition is fairly vague, especially because some recent studies show that even a site with apparently hard, but cracked, rock may still have significant amplification compared to true solid bedrock. As a rule of thumb, "good" bedrock is rock hard enough to prevent any manual digging. If profiles are available, P-wave velocities should be higher than 2 km/s.

Seismic vaults are on average 2 to 6 m (7 to 20 feet) deep. At sites where the solid, non-weathered bedrock is outcropping, the required depth is defined solely by the space required for the equipment. One meter (3 feet) or even less may be adequate if the requirements regarding temperature changes associated with the local climate allow. On some highly weathered rock sites, the required vault depth may exceed 10 m (30 feet). In some places a reasonably deep seismic vault can not reach bedrock at all and a borehole installation would ideally be required. Vaults are sometimes still used in such cases for financial reasons. More details on borehole installations are given in 7.4.5.

### 7.4.2.3 Seismic soil-structure interaction and wind-generated noise

The ideas behind the design and construction of seismic stations have greatly evolved in the last few decades. The increased sensitivity of seismometers and the complexity of seismic research, based more and more on waveforms, require very quiet sites and distortion free records. Sixty years ago, seismic stations were usually situated in houses and observatories. Sensors were installed on large, heavy concrete piers, mechanically isolated from structural elements of the buildings, sometimes well above the ground (see Figure 4.2 in the old MSOP; Willmore, 1979; or <http://www.seismo.com/msop/msop79/sta/sta.html> via link “Examples of stations”). Scientists increasingly observed that the interaction between surrounding soil and civil engineering structures in such installations substantially modified seismic signals during seismic events, particularly if the site was on relatively soft ground. Structures swinging in the wind also caused undesired seismic noise, and strong unilateral wind load or insolation on a building’s walls or the rock face of seismometer tunnel entries caused intolerable drifts in long-period or VBB records.

Further evidence arose (Bycroft, 1978; Luco et al., 1990) that every structure at a site modifies seismic waves to some extent. Therefore, today’s seismic stations are mostly ground vaults jutting only a few decimeters (about a foot) above ground level. All buildings, antennae and other masts are positioned well away from the vault to minimize the interaction.

In theory, there is no modification of the seismic signal by the soil-vault structure interaction if the vault's average density (taking into account the empty space in the vault) equals the density of the surrounding soil. However, seismic station design is never based on calculated average densities. The most important factors are that:

- the design is not too heavy, particularly if the surrounding soil is soft;
- all potential buildings and masts are placed away from the seismic vault;
- the vault rises above ground level as little as possible to minimize wind-generated seismic noise.

### 7.4.2.4 Other noise sources

We recommend that seismic stations are fenced, despite the fact that fences usually represent a significant expense. There are a few exceptions, such as stations in extremely remote desert or mountain sites. The fence minimizes seismic noise caused by human activities or by animals that graze too close to the vault. It also contributes to the security of the station.

The optimal size of the fence depends on several factors:

- density of population around the site and human activity close to the station;
- potential agricultural and other activities in the near vicinity;
- the probability of animal interference;
- general seismic noise amplitudes at the site (quiet stations require a bigger fenced area);
- seismic coupling between ground surface and bedrock. Non-consolidated surface ground and seismometers installed on good bedrock allow a smaller fence. A very deep vault has a similar effect.

The smallest recommended fenced area is 10 x 10 m (30 x 30 feet). In the worst case, a fence could be 100 x 100 m (300 x 300 feet). A height of about 2 m (6 - 7 feet) should be sufficient. Light construction with little wind resistance is preferable so that wind-generated seismic noise is minimized.

The equipment and the vault itself can also generate seismic noise. Equipment that includes mains transformers or rotating electromechanical elements like disk drives, diskette drives, cooling fans, etc. should be installed on the vault wall rather than on the seismic pier.

If the vault cover is not firmly fixed to the vault, it can swing and vibrate in strong winds, which can totally ruin seismic records. Be sure that the cover is very firmly fixed to the top of the vault, as its own weight may not be sufficient to prevent vibration in strong wind. When closed and strongly shaken by hand, there should be no play whatsoever between the vault and the cover. If there is, it will cause seismic noise during strong winds.

If a seismic station uses an antenna mast, place it well away from the vault to prevent seismic noise being generated by the antenna swinging in the wind. The required distance is usually between 5 and 50 m, depending on a number of factors such as:

- the maximum expected wind speed and the probability of windy weather at the site (the higher the speeds and the more often they appear, the greater the required distance);
- the antenna's height (the higher the antenna mast, the greater the required distance);
- the vault's depth (the deeper the vault, the smaller the distance);
- the degree of seismic coupling between sensors and antenna base (strong coupling requires larger distances); and
- general seismic noise at the site (very quiet sites require larger distances).

#### **7.4.2.5 Electrical grounding**

A grounding system is required for the proper functioning of electronic equipment. Grounding of equipment and cables keeps the instrument noise low. It is also a prerequisite for lightning-protection equipment and for interference-free RF telemetry. The grounding system design is usually a part of the RF link design in telemetry seismic systems.

A ground impedance below 1 ohm is usually desired. Generally, a radial star configured system, of five to six "legs" with 15 to 20 m (45 - 60 feet) length each, is required for a grounding system (see Fig. 7.47). The total length of the required grounding metal strips depends strongly on climate and local soil type and its humidity. The strips, made of zinc plated iron or copper, 3 x 30 mm (1/8" x 1.5") in cross-section, should be buried from 25 to 35 cm (~1 foot) deep in the soil. In dry regions they should be deeper. The strips should be straight. No sharp turns (around rocks, for example) are allowed because this decreases *lightning protection* efficiency as a result of increased inductivity of the grounding system.

In arid regions, high deserts, or completely stony areas, longer and thicker strips are required. In these cases, a different approach to grounding and lightning protection is sometimes taken by trying to obtain an electric equipotential plane all around the station during lightning strikes. Grounding impedance is no longer the most important issue. High lightning threat regions and very dry or rocky ground usually require a specially-designed grounding system.

In seismic vaults without metal walls, bury a loose mesh made of grounding strips around the vault and connect them to the rest of the grounding system. The grid dimension of this mesh should be around 60 to 100 cm square (~2 to 3 feet square).

**Fig. 7.47** An example of a seismic station grounding system. Note that its dimension depends on local soil humidity conditions.

At seismic stations with RF data transmission and antenna masts, the star-configured grounding system should be centered on the antenna mast, not on the seismic vault. The seismic vault should be included in one of the legs of the grounding system. One of the grounding strips must be laid exactly above the cables connecting the antenna mast and seismic vault (see Fig. 7.47, detail A). This ensures a minimum voltage drop along the cables during lightning strikes and therefore a minimum induced voltage surge in the cables.

The antenna mast itself should be grounded and equipped with a lightning protection rod. Its highest point should be at least 1 m (3 feet) above the highest antenna or solar panel installed on the mast.

Note that any grounding system requires periodic service checks because contacts between the metal parts may slowly corrode. It is recommended that the grounding impedance of the system be checked once every two years. Regular maintenance visits should always include a check of the lightning protection system and equipment and replacement of any burnt-out elements. For more on lightning protection see <http://www.protectiongroup.com/Home>.

#### 7.4.2.6 Vault construction

Seismic vaults can be made with metal walls. Plain iron sheets or corrugated iron can be welded together, or pieces of large-diameter metal pipes can be used. We recommend zinc-plated metal for durability. It is not necessary to make metal vaults very strong and heavy. Water tightness is relatively easy with this design.

If the vaults are made from thin sheet metal (a few mm), then pour relatively thin, 15 - 20 cm (6 - 8") concrete walls around the metal to add strength. The quality and homogeneity of this concrete does not need to be high because water tightness is not a problem. Locally-available sand aggregates can be used in most cases. Such vaults, however, may cause problems if deformation and tilts of the vault due to external temperature changes are important.

The walls can also be made of only concrete – in which case it is easiest to make the vault rectangular. Note that the quality of the concrete must be good to make the vault watertight, as explained earlier. Apart from very deep vaults, strength is not a problem and therefore no steel reinforcement is needed.

At sites where accessibility allows, vaults can be made of the prefabricated concrete pipe sections used in sewerage systems. They are cheap and can be obtained in different diameters and lengths. In deeper vaults you can simply stack them to the required depth of the vault. Care must be taken to ensure that the joints between sections are watertight.

The bottom of the seismic vault – the seismic pier - is always made of high-quality, watertight concrete. Special requirements must be fulfilled for VBB sensors. More details are given in 7.4.2.1 above.

The depth of seismic vaults is determined by seismo-geological parameters. Apart from providing adequate space to put all the equipment, the diameter is primarily a matter of the desired ease of installation, maintenance and service.

For three-component stations with single component sensors, between 1 and 1.5 m<sup>2</sup> (10 to 15 square feet) of space on the seismic pier is required. Less space is needed for three-component seismometers, three-component accelerometers, or a single component sensor. If the vault contains (or will contain in future) three-component weak-motion and strong-motion sensors, about 1.5 - 2 m<sup>2</sup> (15 - 20 square feet) is required.

We have found that a minimum vault diameter for installation and maintenance is 1.4 m (4.5 feet). If the vault is deeper, a 1.5 to 1.6 m (5 to 5.5 feet) diameter is recommended. Deep vaults (> 4 m (13 feet)) require a diameter of at least 1.6 to 1.7 m (5.5 to 6 feet). Vaults deeper than 1.2 m (4 feet) require a ladder.

#### **7.4.2.7 Miscellaneous hints**

##### ***Vault cover design***

A seismic vault cover should have the following:

- at least 5% slope so that water drains quickly;
- vertical siding all around that extends at least 15 cm (6") below the upper rim of the vault to prevent rain from entering in windy conditions;
- a mechanism which firmly fixes the cover to the ground and a lock to mitigate vandalism;
- handles for easy opening and closing;

- be painted a light color, preferably white, that will reflect as much sun as possible, particularly in hot and dry desert regions.

The metal cover and thermal insulation cover of the vault should not be too heavy. They should be designed in such a way that a single person can open and close the vault smoothly and easily. Otherwise, maintenance visits will require two people in the field. For large vaults, the cover can be designed in two parts, or a simple pulley system may help.

### ***Alternative materials***

As material for a vault cover, metal is less appropriate in very hot and very cold climates as it becomes difficult to handle under extreme temperature conditions. UV light-resistant plastic or water-resistant plywood is a better alternative in dry regions. Plywood also has lower thermal conductivity, which improves thermal insulation, and less weight, making handling the cover easier.

### ***Mitigating vandalism***

Experience shows that, apart from political instability in a country, most vandalism of seismic stations is driven by people's curiosity. Therefore we believe that a large sign with a short and easy-to-understand explanation of the purpose of the station and posted at the entrance to the fenced area, may significantly mitigate vandalism.

### ***Fixing seismometers to the ground***

In regions where earthquakes with peak accelerations of 0.5 g or more can occur, seismometers must be firmly fixed to the seismic pier, a common practice with strong-motion sensors. Obviously, sensitive seismometers are clipped during very strong earthquakes. However, they should not shift or move during such events otherwise, the sensors will not be properly orientated for the recording of aftershocks .

## **7.4.3 Seismic installations in tunnels and mines (L. G. Holcomb; 2002)**

Abandoned mines have been used for many years as ready-made quiet sites for installing seismic instrumentation. In some cases, active mine tunnels have proven to be successful, even though they may be somewhat noisy as a result of mining activity during the workday.

Existing tunnels in solid rock provide a low-cost, ready-made and accessible facility that often provides nearly ideal conditions for the installation and operation of high sensitivity seismic sensors. The bedrock in a mine tunnel is usually already exposed, providing an excellent firm foundation on which to install standard surface instruments. If unventilated, as is usually the case for abandoned mines, a mine tunnel provides an essentially constant-temperature environment that is ideal for seismic sensors. Depending on its thickness, the overburden above the mine tunnels provides isolation of the seismic sensors from the seismic noise that is always present at the surface of the Earth.

Obtaining permission to use an abandoned mine property may be difficult, even for non-working mines, because the operational organization or the property owners may quite understandably be reluctant to allow access because of legal liability. Access to working

mines is usually even more difficult because the additional equipment and personnel involved in station activities tend to interfere with mining activities.

Mines are usually concentrated in mineralized zones. It is therefore unlikely that an existing mine will be found near the location of a proposed seismic installation. Tunnels are sometimes constructed solely for the purpose of the installation of seismic sensors. Digging tunnels in hard rock is a very expensive endeavor because tunneling on a small scale is highly labor-intensive.

In many respects, a tunnel installation is very similar to a surface vault installation. A poured concrete floor or pier is usually constructed on the rough bedrock floor of the tunnel to provide a flat and level surface on which to install the sensors. Despite the improved temperature stability found in a tunnel, it is still necessary to provide adequate thermal insulation around the sensors themselves in order to reduce thermally generated noise. Some type of air pressure variation reduction system is also necessary for long period sensors because the air pressure varies in underground tunnels. Usually, this is accomplished in the same manner as it is in a surface installation although sometimes an effort is made to seal off all or parts of the tunnel itself. Sealing a volume enclosed by natural rock walls is difficult because most tunnel walls are riddled with fractures.

However, there are significant differences between surface vault installations and tunnel sites. Rockfall is a real hazard in a tunnel installation. Both personnel and instrumentation must be protected at the actual location of the instruments and along access routes. Another hazard is the build up of harmful gasses (bad air) underground if the tunnel is not adequately ventilated.

The presence of water and high humidity levels in most underground passages is a common problem in tunnel installations. It is very difficult to keep instrumentation dry and the wet environment is frequently unpleasant to work in. The high humidity slowly corrodes the contacts in delicate electrical connectors, which frequently causes poor electrical contact and intermittent operation. The presence of moisture also slowly degrades the effectiveness of thermal insulation materials, and precautions must be taken to prevent moisture accumulation in the isolation system.

Access to power and communication lines is usually more difficult in tunnel installations, depending, of course, on how far the equipment is placed in the tunnel. Frequently, power and or communication lines must be installed throughout the entire length of the tunnel. In the case of power, this can be quite expensive if long distances are involved; either large diameter cables or a high voltage line coupled with a step-down transformer must be installed to ensure that sufficient voltage is available at the site.

Determining the orientation of an underground sensor is considerably more difficult than in a surface installation. Usually, one must transfer an already known azimuth from outside the tunnel to the installation site using standard surveying techniques. Specially designed gyroscopic systems can be used to determine the orientation underground but they are relatively expensive.

It is more difficult to provide timing to a tunnel site than to a vault. This is particularly true for modern GPS based timing systems because the distance between the antenna (outside the tunnel) and the timing receiver is usually limited. Inline radio frequency amplifiers can be used for long antenna runs. It is preferable, however, to place the GPS receiver near the antenna, e.g., at the tunnel entrance. A serial connection can then be used between the

receiver and the recorder either using RS422 (up to 1 km distance) or fiber optic cable. This approach has been used successfully in the Swiss digital seismic network.

#### **7.4.4 Parameters which influence the very long-period performance of a seismological station: examples from the GEOFON Network (W. Hanka, 2002)**

##### **7.4.4.1 Introduction**

The goal for a very broadband (VBB) station for the GEOFON network is to resolve the full seismic spectrum from high frequency (regional events) to very long period (VLP) (Earth's tides) with sufficient dynamic range. The overall instrument noise should remain below the New Low Noise Model (NLNM, Peterson 1993) throughout this frequency range. The GEOFON project (Hanka and Kind, 1994) aims to achieve this goal at minimum cost. This sets strict limits on costs for instrumentation, vault construction and remoteness of the sites.

It is relatively straightforward to get good station performance in the high frequency and medium-period band since the "only" measures to be taken are to get away from man-made noise sources and the sea shore and find a station site on as hard rock as possible. Good VLP performance is usually much more costly to achieve since adequate instrumentation and vaults with sufficient overburden or borehole installations are necessary. However, there are certain measures which can be taken to optimize the VLP station performance in shallow vaults. The parameters to be taken into account for good VLP performance are:

- Instrumentation
- Installation of instruments
- Vault construction
- Geology
- Depth of burial
- General climate

The influence of these different parameters will be demonstrated in the following case studies from the GEOFON network.

##### **7.4.4.2 Comparison of instrumentation and installation**

###### ***Which seismometer to choose?***

The longer the period of ground motion to be recorded, the larger the potential influence of environmental disturbances, such as temperature and air pressure fluctuations and induced ground tilts on the seismic recording, and the larger the need for effective shielding against them. The instrument currently with the best VLP resolution is the Wielandt-Streckeisen STS1/VBB (Wielandt and Streckeisen, 1982; Wielandt and Steim, 1986). It is widely deployed in the IRIS GSN and GEOSCOPE global networks as well as in some regional networks (e.g., MedNet). The permanent GEOFON network uses mostly Wielandt-Streckeisen STS2 and a few STS1/VBB instruments (see DS 5.1) with comparably good results. Fig. 7.48 shows the resolution of the STS1/VBB and the STS2 in relation to the New Low Noise Model by Peterson (1993).

**Fig. 7.48** A representation of the bandwidth and dynamic range of a conventional analog (WWSSN short- and long-period) and digital broadband seismographs (STS1/VBB and STS2 with GEOFON shielding, respectively). The depicted lower bound is determined by the instrumental self-noise. The scale is in decibels (dB) relative to  $1 \text{ m/s}^2$ . Noise is measured in a constant relative bandwidth of  $1/3$  octave and represented by "average peak" amplitudes equal to 1.253 times the RMS amplitude. NLNM is the global New Low Noise Model according to Peterson (1993).

The more compact, lighter and cheaper triaxial STS2 has a pass band with a slightly higher low-frequency corner (0.00833 Hz instead of 0.00278) and a significantly higher high-frequency corner (dashed lines in Fig. 7.48). Depending on the properties of the recording system, 50 Hz can easily be reached compared to the 10 Hz of the STS1. For nearly all sites on Earth, a properly installed STS2 seismometer will give nearly the same performance as a set of STS1/VBB seismometers. The maximum long-period resolution can only be achieved when the seismometers are properly shielded.

The GEOFON project exclusively uses Wielandt-Streckeisen seismometers. The discussion above and below reflects this fact and is not an endorsement of one make of seismometer over another. Potential instrument purchasers need to establish for themselves what instruments are best suited for their own purposes.

The discussion of the shielding efficiency at GEOFON stations in surface or shallow depth vaults or tunnels in the next Chapter is only based on the VLP channel plots (sampling frequency 0.1 Hz) of STS1 records (original or simulated from STS2 records by recursive filtering). The low self-noise of the STS2 allows us to effectively simulate STS1/VBB records down to tidal periods. Fig. 7.49 illustrates this using the recordings of a tidal wave recorded by an STS1/VBB and an STS2. It is difficult to tell the difference between them.

**Fig. 7.49** Tidal recordings of STS1/VBB and STS2 do not differ very much when properly installed in a comparable environment. The two traces were recorded in the Eastern Mediterranean in buried vaults in limestone. At the station EIL (Eilat, Israel) an STS2 with additional GEOFON shielding and at ISP (Isparta, Turkey) a set of STS1/VBB are installed.

### ***Installation of an STS1/VBB***

Seismometers must be shielded against environmental influences, namely pressure and temperature variations as well as magnetic disturbances. The proper installation of an STS2 to achieve good VLP performance is discussed in detail in the next paragraph. Comments on installing the STS1/VBB are kept short here since this is a well known procedure and is described elsewhere (Wielandt and Streckeisen, 1982, Holcomb and Hutt, 1992).

The three separate STS1/VBB components are supplied with different shieldings: a permalloy helmet as magnetic shield (vertical only), an aluminum helmet and a glass bell jar for evacuation. The feedback electronics are placed in a separate container. There are two basic methods used for the installation of STS1/VBB seismometers. The "conventional" one, also suggested by the manufacturer, uses a plane glass plate which has to be cemented to a plane pier. The second method, introduced by Albuquerque Seismological Lab, uses a warp-free rigid stainless steel base plate (similar to the aluminum one used in the GEOFON STS2 shielding) on which the vacuum glass bells and the metal helmets are installed above the actual seismometer. The second method is faster and easier in practice and gives additional flexibility (see Holcomb and Hutt, 1992).

### ***Installation of an STS2***

The STS2 is not supplied with any shielding. All three components and the electronics are contained in a single casing. This casing provides magnetic and pressure shielding to some extent. Nevertheless, temperature shielding is still important in order to obtain longer period signals with a good signal/noise ratio. This is especially important because of thermal convection generated by heat from the electronics. A rather sophisticated shielding (see Fig. 7.50 a) was introduced by Wielandt (1990) for the first STS2 based network, the German Regional Seismograph Network (GRSN). The STS2 was installed on a 10-cm thick gabbro plate covered by an airtight aluminum helmet. Before being covered, the STS2 is insulated with a thermal blanket.

A simpler and more practical approach is used for GEOFON stations (see Fig. 7.50 b). This uses an aluminum casing consisting of a rigid thick base plate (3 cm) and a thinner aluminum helmet with a cylindrical foam rubber insert. As with the gabbro plate, the base plate can not be easily distorted by pressure variations and gives, together with the foam rubber insert, extra thermal stability. In addition, this shielding helps prevent corrosion and is separated from the pier or ground surface by adjustable tripod screws.

The GRSN shielding has extra internal cabling and a socket, whereas the GEOFON casing does not, and the casing is penetrated by the original STS2 cable through a special hole which is made tight with silicon. The GEOFON shielding potentially gives better electrical performance but has worse pressure integrity. The GEOFON shielding is portable and readily available which are problems with the GRSN shielding.

Even better thermal insulation than the one discussed above can be achieved for both installation methods when an additional styrofoam box, completely filled with styrofoam pieces, is used (as shown in Fig. 7.50 b). The box should be tightly glued to the pier or ground surface and the box lid glued to the box walls after filling with the styrofoam beads. Depending on the site conditions, this can give an additional order of magnitude in VLP noise reduction.

**Fig. 7.50 Left:** GRSN shielding after Wielandt (see Fig. 5.16 in Chapter 5) and **right:** GEOFON type shielding for the STS2.

Fig. 7.51 shows the substantial LP and VLP noise reduction which can be achieved even by an incomplete GEOFON type shielding (aluminum casing only, no polystyrol box) in the period range from 30 to more than 10,000 seconds. A reduction of about two orders of magnitude in terms of spectral power (one order of magnitude in terms of amplitude) can clearly be seen between 100 and several thousands of seconds and again around 10,000 sec.

The GRSN shielding gives exactly the same result in most cases. It is only in very rare situations - probably in connection with large air pressure variations – that the performance of Wielandt's approach is slightly better at periods of several hundreds of seconds.

**Fig. 7.51** VLP noise reduction achieved by using the simpler version of the GEOFON shielding method (no additional polystyrol box and beads ). The relative noise power spectra of the vertical component of two STS2s positioned side-by-side are shown. No instrument correction has been applied. The black spectrum is from the unshielded STS2, the red spectrum from the shielded one.

#### 7.4.4.3 Comparison of vault constructions, depth of burial, geology and climate

The harder the rock and the deeper the vault and the more stable the temperature and air pressure remain in the vault, the better is the VLP performance of a VBB station. In contrast, the shallower a vault is, the greater the influence of the general climate.

Fig. 7.52 shows the scheme of an artificial tunnel vault which is used at several IRIS/USGS installations in cases where no other existing underground facility can be used. The tunnel is about 25 m long and segmented using four doors (air locks). The last chamber contains the large seismometer pier. Since the tunnels are drilled into mountain slopes, depth of overburden is of the order of the tunnel length.

#### *Tunnel vaults*

**Fig. 7.52** Sketch of an artificial horizontal tunnel construction with different chambers to host a VBB seismological station. This type of construction is widely used within the IRIS/USGS

part of the IRIS GSN network. The total length of the tunnel is approximately 25 m. The construction cost of such a vault can reach up to US\$ 100,000 depending on local conditions and infrastructure.

Although the vault construction is identical, the VLP performance at different sites is not. This is shown by the recordings Earth's tides in Fig. 7.53. The tunnel of the IRIS/GEOFON station LVC (Limon Verde, Chile) is built in hard basaltic rock and the traces show remarkably low VLP noise, while at KMBO (Kilima Mbogo, Kenya, also an IRIS/GEOFON site) a soft volcanic conglomerate drastically increases the noise, especially on the horizontal components. Another effect which can clearly be seen on the horizontal components is the large day-night noise variation. The general temperature increase and perhaps also the deformation of surface rocks caused by direct sunshine during the day, as well as stronger winds cause substantially larger VLP noise levels on the horizontals at both sites. This shows that even this kind of sophisticated and expensive tunnel vault construction gives no guarantee of seismic recordings free of environmental influences.

**Fig. 7.53** Comparison of two 3-component STS1 VLP traces recorded in identical tunnel constructions but in different geological and climatological environments. LVC (Limon Verde, Chile) is built in hard basaltic rock in a full desert environment, KMBO (Kilima Mbogo, Kenya) is placed in rather soft volcanic conglomerate influenced mostly by a humid tropical environment. Day-to-night temperature gradients are high in both cases.

#### ***Shallow vaults***

If tunnel vaults are not affordable, other less expensive methods of getting the seismometers sufficiently buried have to be used. Several cases are discussed below.

Fig. 7.54 compares the recordings made at three different stations. The depth of burial is only about 4-5 m in all cases, which is very poor compared to tunnels. Nevertheless, the moderate climate at MORC (Moravsky Beroun, Czech Republic) and at ISP (Isparta, Turkey) gives a relatively good VLP performance. These vaults are built in hard rock and limestone, respectively. The spikes which can be seen mainly on the horizontal traces are due to human activity close to the site. In the arctic climate of KBS (Ny Alesund, Spitzbergen = Svalbard), the more drastic temperature changes cause increased VLP noise level on the horizontals. Here, there are also some spikes caused by local man-made disturbances.

**Fig. 7.54** Comparison of three 3-component VLP records in shallow vaults (4 - 5 m). At MORC (Moravsky Beroun, Czech Republic) an STS2 is installed in a 1 m wide borehole in hard rock; in ISP (Isparta, Turkey) and KBS (Ny Alesund, Spitsbergen) sets of STS1/VBB are installed in underground bunker vaults in limestone and weathered rock (permafrost), respectively.

The vaults at KBS and ISP are very similar: about 5 m deep large underground concrete bunkers with large concrete piers for the installation of the STS1/VBB seismometers (see Fig. 7.55 a). The geologies are different: weathered rock in permafrost (KBS) and limestone (ISP). The recording system at KBS is located elsewhere, while at ISP, recording is local in a house built above the vault. A very different construction is used at MORC: a very wide shallow vertical borehole has been drilled into hard rock and a one-meter wide steel tube placed into

it, with a concrete floor on the bottom. The STS2 in GEOFON shielding has been installed on this at about 5 m depth (see Fig. 7.55 b). Here and in the two other examples of construction schemes for STS2 stations (see Figs. 7.55 c and d), a recording room hosting all computer and communication equipment is located above the seismometer vault.

**Fig. 7.55** a) Underground bunker vault construction for the installation of a set of STS1/VBB (remote recording); b) "wide & shallow borehole" vault construction for the installation of an STS2; c) and d) simple bunker vault construction schemes for an STS2. The vault constructions b - d allow onsite data recording thanks to the existence of a separate recording room.

Fig. 7.56 shows, again in comparison to MORC, the recordings at shallow vaults in locations near the equator. At PMG (Port Moresby, Papua New Guinea) a two-room underground vault hosts a set of STS1/VBB seismometers. The two-room construction is situated in a sedimentary layer above rock and is comparable in size with the one at KBS and ISP, but shallow (3 m) and with a horizontal entrance into the first (recording) room. UGM (University Gadjadara, Yogyakarta, Indonesia) uses a very simple, 2.5 meter deep bunker in limestone (construction after Fig. 7.55 c) with an STS2 and a small open recording hut above. Both show rather similar results to MORC, especially on the horizontals. The extreme large amplitudes at UGM during daytime are caused by human activity close to the station.

**Fig. 7.56** Comparison of three 3-component VLP records from shallow vaults in rock in different climates. Data from two sites close to the equator (Port Moresby, Papua New Guinea, PMG, and Wanagama, Indonesia, UGM) are shown together with data from MORC (same station as in Fig. 7.54).

In principle, the VLP station performance is not so different at both equatorial sites, particularly the horizontal components which are not as good as at a site in a more moderate climate. The instrumentation and construction details do not play any significant role in determining the VLP noise performance.

#### ***Surface vaults in moderate climate***

The STS2 records in Fig. 7.57 were obtained in a simple above-surface vault on rock (DSB) and a very shallow vault in soft sediments (RGN). Both sites are located in an area with a very moderate climate and close to the sea. Temperature shielding is a little better at RGN due to complete soil coverage on three sides and up to one meter on top. Therefore the general VLP performance - as seen on the vertical components - is better at RGN, but the horizontals show large additional distortions during daytime. These are most likely caused by temperature-induced swelling and related up-bending of the sand hill which is a very typical behavior for sediments (it can also be seen to some extent on the PMG records in Fig. 7.56). This is not the case with rock at DSB. It is remarkable that there is almost no day-night variation on the DSB records although the vault is completely above the surface. This is due to the maritime climate with very small day-night temperature changes.

**Fig. 7.57** Comparison of two surface vaults in moderate climate on rock and in sediments. At DSB (Dublin, Ireland), a small surface bunker was built in an old granite quarry. At RGN (Rügen Island, Germany), an old one-room military bunker with a thin ( $< 1\text{m}$ ) soil cover on top is used. Both sites host STS2 seismometers with GEOFON shielding.

#### ***Surface vaults in arctic climate***

The very poor VLP noise performance of surface stations in arctic climates can be seen in Fig. 7.58, where data from two stations in Greenland are shown. Both vaults are located in surface wooden huts built on weathered rock, more or less open to all kinds of atmospheric turbulence in terms of air pressure and temperature changes. The vaults are heated in winter. This results in about the worst conditions one can imagine for VLP noise performance. Earth's tides are no longer seen very clearly and the daily noise variations are large. However, there is no other choice in these regions. DAG is in one of the most remote places on Earth where it is almost impossible to build an underground vault.

#### **7.4.4.4 Conclusions**

The VLP performance of a VBB seismological station is directly dependent on several instrumental and environmental parameters. High quality VBB seismometers, a true 24-bit A/D converter and a continuous multi-stream data recording are essential. In the GEOFON network, only STS1/VBB and STS2 seismometers and Quanterra data loggers are used for this reason. With the appropriate shielding, the VLP performance of the STS2 is not much different from the STS1/VBB. Only in very rare cases at extremely quiet sites can the extra infrastructure, installation, maintenance and financial efforts related to the usage of STS1/VBB sensors be justified. The same is true for vault construction. The construction

scheme itself has not much influence on the station performance as long as the depth of burial is deep enough and the environmental disturbances can be reduced to a minimum. With an adequate casing, a seismometer pier is not required to install an STS2 sensor properly underground. The geology plays a very important role. The harder the rock, the lower is the VLP noise at a certain depth since surface tilts caused by atmospheric influences do not penetrate as deep. Sediments show special tilting effects, which reduce drastically the daytime VLP performance of the horizontal components. The shallower a vault is, the more the influence of the general climate. In very moderate climates, e.g., close to the sea, even surface vaults can have a reasonable VLP noise level. In summary: Although the task of establishing a VBB station that is capable of recording with sufficient dynamic range the full seismic spectrum from high-frequency regional events up to the very long-period (VLP) Earth's tides seems to be a very difficult and costly effort, it can be achieved with rather simple means.

**Fig. 7.58** VLP records obtained at two surface vaults on Greenland. At DAG (Danmarkshavn, NE Greenland) a STS2 in GEOFON shielding is installed in a wooden hut on weathered rock close to the sea shore. At SFJ (Sondre Stromfjord, SW Greenland) a set of STS1/VBB is located in a container-like building on top of a mountain. In both cases the geology is weathered rock in a permafrost environment.

More details on the installations made at various VBB stations and the comparison of noise data can be found on the web page <http://www.gfz-potsdam.de/geofon/>.

## **7.4.5 Broadband seismic installations in boreholes (L. G. Holcomb, 2002)**

### **7.4.5.1 Introduction**

Borehole seismology is a relatively new technology that has developed over the last 30 years or so. In the early years of seismology, installing a seismometer in a borehole was virtually impossible because of the relatively large physical size of instruments. As seismological technology matured, the instruments became smaller and it became more practical to consider borehole installations as alternatives to surface vaults or tunnels. There are several practical reasons for placing seismic instrumentation in boreholes; these include reduced noise levels, temperature stability and reduced pressure variability.

Experience gained over many years of installing both short- and long-period instruments has shown that sensor systems which are installed at depth are usually quieter than those installed at or near the surface of the Earth (see 4.4.). This is why abandoned underground mines are frequently used as sites for low-noise seismological stations. However, abandoned mines are not always found at the desired location of a seismic station. A borehole provides a practical solution to the need to install seismic sensors at depth almost anywhere.

A borehole is also a very stable operating environment in which to operate sensitive instruments because the temperature at depth is very stable and the pressure in a cased sealed borehole is very constant. Temperature changes and pressure variations at frequencies within the pass band of the sensor system are common sources of seismic noise (see 7.4.2.1). Systems installed on the surface or in shallow vaults require extensive thermal insulation systems in order to reduce the influences of temperature to acceptable levels. Similarly, elaborately designed pressure containers are required to eliminate pressure-induced noise particularly at long periods in vertical instruments. Both temperature and pressure considerations have become more important with the advent of broadband instruments because these instruments are sensitive to outside influences over a broader frequency range thereby making it more difficult to sufficiently isolate broadband instruments from extraneous influences. A sealed borehole of only moderate depth provides excellent temperature stability because of the tremendous thermal mass and inertia of the surrounding Earth. Furthermore, most seismic boreholes are cased with steel casing whose cylindrical walls are quite thick; this casing constitutes a quite rigid container, which greatly reduces atmospheric pressure variations within the borehole (assuming that both the top and bottom are sealed).

Boreholes are frequently considered to be expensive, but they sometimes represent the only practical alternative if an abandoned mine is not available. Excavating tunnels purely for seismological purposes into competent rock deep enough to provide sufficiently quiet seismic data is also a very expensive solution (see below). In many cases, a borehole may actually be the cheapest method for achieving an installation at depth unless the local manual labor costs are very low.

One advantage of a borehole installation over a vault is that there can be much less surface equipment on site, especially if no recording equipment is deployed on the site, say in a seismic array or small network. This can significantly save on costs and improve security. These advantages have led, in some cases, to the use of very shallow boreholes, or postholes, which are drilled to depths similar to vaults.

It is impossible to state exactly how much it would cost to construct either a borehole or a tunnel type vault because too many factors are involved. Precise costs will depend on the type

of material in which the facility is constructed, raw material costs, local labor costs, etc.. However, here are some examples of approximate costs that have been encountered in constructing facilities for the IRIS program over the past 5 to 10 years. In Africa, IRIS has excavated three tunnel type seismic vaults that extended 25 to 40 meters horizontally into hillsides. The costs of these three projects ranged from approximately US\$ 150,000 to US\$ 250,000. For a typical borehole (100 meter deep), project costs range from approximately US\$ 25,000 to US\$ 200,000 at large landmass sites with boreholes in hard rock being significantly more costly than in soft soil. On the other hand, at small isolated Pacific Ocean island sites, borehole costs are in the US\$ 150,000 to US\$ 250,000 range.

#### **7.4.5.2 Noise attenuation with depth**

The main reason for installing broadband sensors in boreholes is to reduce the long-period tilt noise which plagues horizontal sensors installed on the surface. The question commonly asked by seismologists who are contemplating a borehole installation is how rapidly does the tilt noise decrease with depth and so how deep does the borehole need to be. There is no easy answer to this question because a borehole never eliminates all of the long-period tilt noise however deep it is. In general, the noise attenuation rate (db per unit depth) decreases as the depth increases; most of the noise reduction occurs in the upper parts of the borehole.

Fig. 7.59 illustrates the attenuation of long-period horizontal noise with depth. It shows the relative power spectral density (PSD) noise levels obtained from the simultaneous deployment of four broadband sensors located close to one another at the same site and installed at various depths. The first sensor was installed in a small vault on or near the surface. Three other three sensors were installed in boreholes at depths of 4.3, 89 and 152 m below the surface. The site consists of about 18 m of unconsolidated (soft/weathered) overburden overlying fractured Precambrian granite bedrock. In Fig. 7.59, noise attenuation data points in db relative to the noise level in the surface sensor are plotted for periods of 30, 100, and 1000 seconds. Note the very rapid decay in the noise level over the first few tens of meters followed by a much slower rate of decrease in noise levels at greater depths. Note that, in general, a depth of 100 m is sufficient to achieve most of the practicable reduction of long period noise.

The data in Fig. 7.59 should only be regarded as an example of noise attenuation with depth. Apparent surface noise levels at a particular site are frequently highly dependent on the methods used to install the instrumentation. This is particularly true of noise levels at many surface installations where faulty installation of broadband horizontal sensors causes excessive tilt noise at long periods.

Choosing the optimum depth for a borehole for a particular site involves comparing the cost of drilling the borehole to a given depth against the desired data quality, the anticipated surface noise levels (they are frequently determined by the anticipated wind speeds and wind persistence at the site), and the depth of the overburden at the site. Unfortunately, studies detailed enough to yield the precise relationships between the various factors have never been conducted. Therefore, choosing the depth of a borehole for a particular site usually involves non-quantitative consideration of the various factors involved. Many years of experience has demonstrated that 100 meter deep boreholes drilled at sites with a few tens of meters of overburden overlying relatively competent bedrock will provide a sufficiently quiet

environment for installing a high quality borehole instrument. Most broadband IRIS borehole instruments are installed at or near 100 meters depth. Boreholes at sites with more overburden and/or softer lower quality bedrock are sometimes deeper depending on construction costs and anticipated surface noise levels.

**Fig. 7.59** Horizontal surface noise attenuation as a function of depth at three selected periods. The depths were 0, 4.3, 89, and 152 meters.

#### 7.4.5.3 Site selection criteria

There are several criteria for selecting the site for a borehole installation. Ideally, one should select a site at which the surface background seismic noise over the band of interest is as low as possible. However, there are other factors such as accessibility, availability of power, improved network configuration, the presence of wide-spread thick alluvial fill, and/or the presence of cultural activity within the monitored area, which may force the choice of a site with higher background noise levels.

A good borehole should penetrate well into bedrock (70 to 100 meters) (see 7.4.2.2), so the site should have bedrock at or near the surface to minimize the need to drill through excessive overburden. If possible, the bedrock should be a relatively hard rock (see 7.1.2.2) such as granite or quartzite. Harder, more competent rock increases the rate of attenuation of surface noise with depth and also decreases the chances of borehole collapse during drilling. Soft rocks such as shale, mudstone, or low grade limestone should be avoided if possible.

Good bedrock is highly desirable for providing the best results from a borehole installation, but benefits are still there for boreholes in poorer rock. Note that the first data point in Fig. 7.59 (only 4 meters down) was obtained in a very shallow borehole that was drilled entirely in loose alluvial fill. Therefore, the lack of shallow bedrock should not preclude the consideration of a borehole installation for a particular site.

As with vault and tunnel installations, a reliable source of electricity will be necessary to power the site, a shelter will be needed to house the recording equipment, and some form of communication capability (telephone line, internet connection, RF or satellite link) is

frequently desirable (see IS 8.2). Accessibility for both the drilling equipment and maintenance personnel (see also 7.1.2.4) should also be considered during site selection activities.

Unfortunately, the need to be able to provide adequate security is also becoming a major factor in selecting station sites in many parts of the modern world. There is little point to investing in a good site if it can not be protected from vandalism. Adequate security has many different meanings depending on the particular situation. It may be as simple as a passive protective fence or as elaborate as alarmed fences and entry ways or even an on-site caretaker depending on the anticipated level of potential damage.

It should be noted that stations on very small islands (such as most coral atolls) do not benefit from borehole installations because the ground motion generated by ocean-wave loading of the beach penetrates rather deeply into the subsurface environment. For this reason, all borehole sites should be at an adequate distance (at least several km) from any coastline.

#### **7.4.5.4 Contracting**

Seismic boreholes are usually drilled by a local contractor using specifications supplied by the organization building the station. Hiring a local driller helps reduce mobilization and setup charges, which are frequently a significant portion of the cost of a seismic borehole. Specifications should be rigid and specific enough to ensure that the finished borehole will be suitable for seismology but flexible enough to prevent excessive costs. Most drilling contractors will have little or no experience of seismic boreholes and it is recommended that the contracting agency use an independent expert with extensive drilling and casing experience whose duties include on-site observation and supervision of all drilling and casing operations. This precaution is advisable to ensure that the drilling contractor performs all operations according to the specifications because departures from specifications are hard to detect, document, and prove after the project is finished. The contract should be specific about who is responsible for unexpected difficulties which might arise during the drilling and casing operations; courses of action should be specified if operations are delayed for any reason whatsoever. These include but should not necessarily be restricted to on-site down time which might be due to bad weather, shortage of drilling materials, crew availability, drill rig breakdowns, loss of circulation, injuries on the job, delays in subcontractor availability, holidays and unexpected changes which might be encountered in the quality of the subsurface rock.

#### **7.4.5.5 Suggested borehole specifications**

The drilling specifications for a seismic borehole should be written in such a way as to ensure that the completed borehole will be suitable for acquiring high quality seismic data. Parameters such as borehole verticality, depth, diameter, and casing type must be clearly specified. It is also important to specify how these parameters will be measured during construction or in the finished borehole.

Borehole verticality is the specification which drillers have most trouble meeting. Borehole verticality must be specified because all borehole seismometers have only a limited range of tilt over which their mechanical internal leveling mechanisms operate. Therefore, the sensor

package must be aligned within a given tolerance from true vertical. This in turn requires that the borehole itself be aligned within a certain tolerance of true vertical. The required verticality specification will depend on which borehole seismometer is to be installed in the completed borehole because each seismometer has a unique mechanical leveling range (typical examples: CMG-3TB has a 3 degrees range, the KS-36000 has 3.5 degrees and the KS-54000 has 10 degrees). In general, the closer the verticality specification requirement is to vertical the higher the cost of the borehole.

The working depth of the borehole is usually specified as the depth of the open cylinder within the borehole confines after construction is complete. The driller is usually left with determining the depth of the hole to be drilled in the rock in order to achieve the desired working depth.

Most boreholes are cased with standard casing used in oil fields because it is readily available throughout the world. This casing is usually specified in terms of its outside diameter (OD) and its weight per unit length; the combination of these two parameters determines the wall thickness and in turn the inside diameter (ID) of the casing. The seismometer manufacturer usually recommends a range of casing in terms of the ID's of the casing in which his sensor will operate satisfactorily. These two methods for specifying borehole diameter must not be confused when writing specifications. As an example of typical hole diameters, a KS-54000 requires a casing with at least a 15.2 cm ID whereas, if equipped with proper hardware, a CMG-3TB (see DS 5.1) will fit into a slightly smaller casing. The specification usually permits the use of a range of OD's and weight specifications in order to facilitate acquiring the casing locally to decrease shipping costs. The individual threaded casing sections should be assembled together with a thread sealing compound and enough torque to ensure that each joint is properly sealed against leakage.

The bottom end of the casing is often equipped with a one way valve (called a float shoe) to seal the lower end against water entry and to facilitate cementing operations. This device allows the cementing mixture to be forced out of the bottom of the casing and prevents water from entering the borehole once the cementing operation is completed.

The casing must be firmly cemented to the surrounding rock walls of the borehole in order to ensure good mechanical coupling. The cementing operation usually consists of pumping a premixed cement mixture down the inside of the casing, out through the float shoe at the bottom, and forcing it back up to the surface between the casing and the bedrock. This operation ensures that all of the annular volume between the steel casing and the rock is filled with cement without voids containing air or liquid. When return cementing mix is observed in the annulus at the surface, a cleaning plunger is forced down the inside of the casing with water under high pressure. This expels the cement mix contained within the casing volume out of the bottom through the float shoe and finally sets (locks) the one way valve within the float shoe to prevent fluids from re-entering.

After the cement has set, it is advisable to require the driller to perform a leak test to ensure that the casing has been adequately sealed. Leak testing usually consists of first pressurizing the water-filled borehole to a specified pressure, sealing it off and leaving the pressurized borehole for a specified time period. The pressure within the borehole should not drop more than a pre-specified amount.

The upper end of the casing is normally terminated with a "packoff" device. This assembly is normally provided and installed by the contracting organization at the time of seismometer

installation. The packoff unit seals the top of the borehole and provides a means of passing instrumentation cables into the borehole.

#### **7.4.5.6 Instrument installation techniques**

It is a relatively simple operation to install a borehole sensor but certain precautions are required. The sensors are usually fitted with two cables. The first cable is intended to provide sufficient strength to lift the weight of the sensor and any extra pulling force required to removing the sensor from the borehole. This is usually a steel cable or "wire rope". The second cable contains the electrical connections for power, control of the various mechanical operations within the sensor, and to transmit the seismic signals back up the borehole. For holes of significant depth, a small lightweight electrically driven winch and mast assembly can be used to lower the sensor into the hole and to retrieve it if necessary. Lowering and raising the sensor should be done fairly slowly because the sensor package sometimes catches on the casing pipe joints as it moves up or down the borehole. On the way down, this problem is usually temporary but usually results in a short free fall of the sensor and a sudden stop when the load-bearing cable becomes taut. If severe enough, the sudden stop can damage a sensitive instrument. If the sensor catches on a pipe joint on the way up, tension in the load bearing cable rapidly increases to dangerous levels if the winch is not stopped in time. If the sensor disengages from the pipe joint while the lifting cable is under high tension, the sensor will undergo possibly damaging levels of acceleration. If the sensor does not disengage and if the winch is powerful enough, the lifting cable may break and endanger personnel.

It is advisable to carry out a dummy run in the completed borehole using a metal cylinder with similar dimensions and weight to the seismometer package. This will help minimize the risk of damage to or losing the equipment during installation. Such a dummy run could be part of the acceptance procedures for the drilling contract.

Traditionally, borehole seismometers are rigidly clamped to the inside of the cased borehole with manufacturer-supplied mechanical hardware to ensure adequate coupling between the sensor and ground motion. The hardware usually includes a mechanically driven locking mechanism for clamping the sensor to the walls of the borehole. This device sometimes consists of a motor driven or spring loaded pawl that is extended on command from the side of the sensor package to contact the borehole wall opposite the sensor (GS-21, CMG-3TB). Sometimes this function is performed by a separate piece of hardware known as a "holelock" that is clamped into the borehole and on which the sensor package is subsequently placed (KS-36000, KS-54000, and earlier Guralp sensors). In the second case, additional hardware is sometimes required to stabilize the upper end of the sensor package (the centralizer assembly in KS instruments). Mechanical clamping mechanisms have been used successfully for many years and have produced satisfactory data from many installations

However, many installations of this type produce more long-period noise in the horizontal components than in the vertical component. In some of these installations, the horizontals were orders of magnitude noisier at long periods than the vertical. The source of the excess noise in the horizontal components has been difficult to isolate and eliminate. For many years, it was suspected that some of this noise was somehow generated by air motion in the vicinity of the sensor package. Conventionally designed horizontal components of long-period seismometers (this includes all sensors with garden-gate type of suspension such as the STS1, CMG-3 series, KS-36000 and KS-54000) are extremely sensitive to tilt because of their inability to separate the influences of pure horizontal acceleration input to the sensor frame

(the desired input) from the signal that arises from the tilting of the sensor package (tilt noise). Therefore, fairly elaborate schemes for reducing the potential for air motion around the sensor within the borehole have been devised and utilized with varying success. Through trial and error, it has become customary to wrap the sensor package (KS-36000's and KS-54000's) with a thin layer of foam insulation in an attempt to somehow modify the flow of heat near the seismometer in the borehole. In addition, it has become common to place long plastic foam borehole plugs immediately above these sensor packages deep in the borehole and near the top of the borehole to block air motion in these sections of the borehole. Additional insulation, which is intended to further reduce air motion within the borehole, is sometimes utilized near the top of the sensor package.

Recently, a highly successful method for significantly reducing the long-period noise levels in borehole installed horizontal components has been developed at the Albuquerque Seismological Laboratory. It consists of simply filling the entire empty air space below and around the sensor package with sand. In this type of installation, none of the auxiliary installation hardware such as the borehole clamping mechanism or holelock, the azimuth ring, the pilot probe, the centralizer, the foam plugs and/or insulation are utilized to install the seismometer. The seismometer package is simply lowered onto a bed of sand at the bottom of the borehole - sometimes, a piece of hardware called a sand foot is installed on the bottom of the sensor. A volume of sand is then poured into the borehole to a depth extending to the top of the seismometer package. The volume required can be easily calculated from the dimensions of the package and the inner diameter of the borehole.

Experimental investigations have demonstrated that it is easy to remove the seismometer from the sand if necessary for maintenance purposes even when the sand is saturated. Normally, the sand left in the hole from a previous installation is not removed from the hole prior to the next installation. Only a fraction of a meter of borehole depth is lost per installation; if necessary, the sand can be removed from the borehole with a downhole vacuum cleaner that has been designed at ASL.

This method of installation is expected to reduce horizontal noise to levels approaching the noise level of the vertical component at any particular site. The horizontals should be expected to always be slightly noisier than the vertical component because remnant real ground tilt will always be present regardless of how deep the sensor is installed. To date, extensive testing at ASL utilizing both KS and CMG (see DS 5.1) instruments and several actual KS sand installations in the field have indicated that sand does indeed produce significantly reduced levels of horizontal noise. The sand installation method has been adopted for future installations by the IRIS GSN program.

One additional advantage of a sand installation is that the seismometer package costs considerably less than for a clamped installation.

One note of caution should be introduced at this point. Conventional hole-lock based installations produce very noisy horizontal data if the sensor package is immersed in water or another liquid such as motor oil. Therefore, every effort is normally made in the field to keep liquids out of the borehole. Although not thoroughly tested to date, sand installations are expected to provide quiet horizontal data even if the sensor is immersed in water as long as the water is not flowing.

Determining the orientation of the horizontal components of a seismometer installed in a deep borehole is not a simple matter because one can not physically get at the instrument once it is

installed. One must resort to indirect methods for determining how the instrument is oriented. For the past 25 years, the KS series instrument installations have relied on a gyroscopic procedure to determine the seismometer orientation as follows. First, the hole-lock is installed in the borehole at the intended operating depth; then, a gyroscopic probe is lowered into the hole and mated with an alignment slot in the hole-lock. The gyro system determines the orientation of this alignment slot with respect to a known azimuth (usually north) on the surface. An adjustable azimuth ring located on the base of the KS sensor is then set to compensate for the alignment of the hole-lock slot to north. This ensures that when the seismometer is lowered into the borehole and the key on the alignment ring is mated with the alignment slot in the hole-lock, the sensor is in a north-south, east-west orientation.

This method was considered adequate to determine the azimuth of borehole installations for many years, but it had some serious shortcomings. The method was subject to errors due to mechanical assembly tolerances and was frequently plagued by nonlinear gyro drift. The major problem with the system was the fragile nature of the gyro probes themselves; they proved to be very susceptible to shipping damage and extremely expensive to repair. In addition, the manufacturer was not willing to warrant his expensive repair work in any way. Therefore, a much cheaper alternate method of orienting borehole seismometers has been developed and is currently replacing the gyro probe approach in programs with limited budgets.

The new method involves the installation of a horizontal reference seismometer on the surface near the borehole at a known orientation. The digitally recorded output of this surface sensor is then compared using the coherence and correlation functions with the digitally recorded outputs of the horizontal components of the sensor installed in the borehole to determine the relative azimuthal orientation of the borehole components with respect to the surface horizontal.

With the advent of sand installations, the horizontal components of newly installed seismometers are no longer being oriented in the conventional north-south east-west configuration. Instead, many borehole sensors are being installed at arbitrary azimuths with respect to north; the alignment of the horizontals with respect to north then becomes part of the data set. This approach has become feasible because modern computing power and digital data trivializes the task of rotating the data to any azimuth desired by the data user.

#### **7.4.5.7 Typical borehole parameters**

As the result of the SRO and IRIS programs, there are now many broadband borehole installations in use around the world. Most of these boreholes are geometrically quite similar because they were designed to accommodate the same seismic instruments. All of these boreholes are approximately 16.5 cm in diameter and most of them are drilled to a maximum of 3.5 degrees departure from true vertical. They are all cased with standard oil field grade casing and most of them are watertight.

There is some variation in the depths of these boreholes. As mentioned above, the vast majority of seismic boreholes are approximately 100 meters deep. However, some of these boreholes are considerably deeper if they were drilled in areas with thick overburden or poor bedrock. For instance, the borehole sensor at DWPF (Florida) is installed at 162 meters depth because the overburden at DWPF is approximately 46 meters thick and the upper layers of bedrock consist of interleaved units of varying grades of soft limestone. The borehole at

ANTO, which is drilled in competent rock for most of its depth, is the deepest and oldest IRIS borehole at 195 meters. This was the first field borehole that was drilled for the SRO program: as more experience was gained, it became apparent that boreholes that deep were not cost-effective. A few of the boreholes are shallower primarily because severe difficulties were encountered during the drilling operations that necessitated finishing the borehole at a shallower depth than originally desired. For example, the sensor at JOHN (Johnson Island) is at a depth of 39 meters because severe borehole collapses were encountered while attempting to drill deeper. The site is on a coral atoll and the surface layers are very poorly consolidated; true bedrock probably lies at very great depths. Drilling in volcanic regions often proves to be very difficult. The borehole at POHA on the island of Hawaii was terminated at 88 meters because the drillers experienced severe "loss of circulation" conditions throughout the drilling operation. The surface layers at POHA consist of badly fractured weathered basalt layers and basalt rubble separated by scoria rubble, ash flows, sand and other assorted debris produced by an active volcano. Drilling conditions in the volcanic deposits on Macquire Island proved to be so difficult that it was impossible to complete a borehole.

#### **7.4.5.8 Commercial sources of borehole instruments**

Currently, there are only two known commercial sources of high sensitivity broadband borehole seismometers. For many years, Teledyne Geotech in Dallas Texas, USA (now Geotech Instruments LLC; [www.geoinstr.com](http://www.geoinstr.com)) was the only source of high sensitivity instruments (KS-36000, KS-54000, GS-21, and 20171) designed specifically for borehole installation. Both the KS-36000 and the KS-54000 are three-component broadband, closed loop force feedback sensors that are designed for deep (up to 300 meters) borehole installation. The GS-21 is a conventionally designed short-period vertical deep borehole instrument intended for superior high frequency performance. The 20171 is a slightly noisier and slightly cheaper version of the GS-21. The KS-36000 is no longer manufactured but there are many of these instruments still in operation in boreholes around the world. Recently, Geotech has introduced a new sensor, the KS-2000, which is available both as a surface package and a 4-inch borehole package.

For the past few years, Guralp Systems Ltd. ([www.guralp.com](http://www.guralp.com)), Reading, UK, has been producing a borehole version of the CMG-3T (see DS 5.1; referred to by some as a CMG-3TB). This instrument is much smaller and much lighter than is a KS sensor; it is also considerably less expensive. This is a three component, broadband, closed loop, force feedback instrument that is very easy to install. Guralp Systems has recently introduced a new borehole sensor that has both a velocity and an acceleration output and is integrated with its own digitizer. In addition, they are willing to work with the customer to meet any specific requirements.

A borehole version of the STS2 has been under development for several years. Currently, a basic prototype of the instrument exists but the instrument requires further development of the remote control functions and the final packaging design is yet to be determined. Streckeisen has not announced an availability date for the new instrument.

It is somewhat hazardous to quote sensor prices because they are continuously subject to change by the manufacturer and international currency exchange rates change daily, but here are some approximate current relative costs for borehole sensors in 1999 US dollars. These prices should be viewed as being approximate; potential buyers should consult the manufacturer for a current quote.

A basic Geotech KS-54000 was priced at nearly US\$ 65,000. Additional costs will be about US\$ 40,000 for a conventional installation or about US\$ 13,000 if installed in sand and if all the associated installation hardware has been purchased. However, this price may be reduced if the instruments are ordered in sufficient quantities (25 or more). A GS-21 was priced at about US\$ 8,000 and the 20171 was around US\$ 6,000 for the instruments themselves. The associated hardware (soft electrical cable, wire rope, winch etc.) is additional. Estimated delivery time for these instruments is 120 days or more after receipt of order depending on the availability of non-Geotech manufactured parts. The soon to be introduced KS-2000 sensor will be priced at below US\$ 10,000 for the surface system and the borehole version will probably be below US\$ 20,000.

A Guralp Systems CMG-3TB costs about \$28,000 if the instrument is to be installed in sand; and about \$39,000 for a hole-lock equipped version. Delivery is currently about 9 months but they are trying to decrease this to about 6 months.

#### **7.4.5.9 Instrument noise**

It is important to remember that the purpose of installing seismic instrumentation in boreholes is to obtain quiet seismic data. This will be foiled if the seismic sensor system itself is too noisy to resolve the lower levels of background noise of the Earth which are expected to be found at the bottom of the borehole. As delivered from the factory, sensor self-noise levels sometimes vary over a wide range and some instruments may be far too noisy to operate successfully in a quiet borehole. Therefore, it is recommended that the self-noise of all borehole instruments be measured before installation to ensure that they are quiet enough to be able to resolve the background noise levels anticipated at the bottom of the borehole. Self-noise measurements are usually made by installing two or more sensors physically close enough together to ensure that the ground motion input to all of the sensors is identical. The data produced by the sensors is then analyzed to determine the level of the incoherent power in each sensor's output; this incoherent power is usually interpreted as the sensor internal noise level (see 5.6). To achieve high fidelity recording of true ground motion, the seismometer system self-noise level should be well below the anticipated background Earth's motion levels across the band of interest at the site.

The low-noise models in Fig. 7.60 can serve as guidelines to the instrument noise levels that may be expected from the CMG-3TB and the KS-54000 sensor systems. In this figure, the CMG-3TB low-noise model (CMGLNM) is the thin solid line and the KS-54000 low noise model (KSLNM) is the thin dashed line. The solid heavy line in the figure is Peterson's (1993) new low-noise model (NLNM) for the background seismic noise at a quiet site. The reader should recognize that there is no single known site in the world whose background power spectral density levels reach NLNM levels across the entire band. Instead, the NLNM is a composite of the lowest Earth's noise levels obtained from many sites. Similarly, the low-noise models for the instruments should not be regarded as being typical of all instruments because each seismic sensor has a distinct personality of its own. Instead, the low-noise models for the instruments should be regarded as lower limits of instrument noise just as is the case for the NLNM of ambient Earth's noise. In all probability, individual instruments will be noisier than the low-noise model for that instrument over at least portions of the spectrum.

The CMGLNM plot in Fig. 7.60 is based on a composite of experimental test data obtained at the Albuquerque Seismological Laboratory over a period of several years. The central portion

(from about 0.6 to about 20 seconds) of the model was not actually measured because of numerical resolution limits of the data processing algorithms and this portion of the model is an estimate. As a general rule, many CMG-3TB instrument noise levels approach the CMGLNM at short periods (less than 0.6 seconds); fewer of these instruments achieve the indicated noise levels at long periods (greater than 20 seconds).

The KSLNM plot in Fig. 7.60 is a factory-derived theoretical instrument noise level. As such, it should be regarded as an optimistic estimate of the lower limits of the self-noise in the KS-54000. Most KS-54000 instruments are probably noisier than the levels indicated by the KSLNM curve.

**Fig. 7.60** Low-noise models for the KS-54000 (KSLNM) and the CMG-3TB (CMGLNM) sensor system self-noise relative to Peterson's (1993) new low-noise model (NLNM) for background Earth's motion.

#### 7.4.5.10 Organizations with known noteworthy borehole experience

As an organization, Teledyne Geotech (Geotech Instruments – [www.geoinstr.com](http://www.geoinstr.com)) certainly has the longest history in seismic borehole technology. However, personnel turnover in the past few years has significantly depleted Geotech's direct hands-on experience in boreholes. Another organization with a long history of borehole experience is the United States Air Force Technical Applications Center (AFTAC – [www.aftac.gov](http://www.aftac.gov)). Over the past 25 years they have deployed many KS instruments throughout the world. Most of these installations involve multiple sensor configurations deployed in arrays. Prior to the KS era, AFTAC used the older Geotech Triax instruments in boreholes at some of their arrays. As was the case with Teledyne Geotech, AFTAC does not have personnel with long-term borehole experience; US Air Force personnel tend to rotate in and out of their duty assignments every two years.

The Albuquerque Seismological Laboratory (<http://earthquake.usgs.gov/regional/asl/>) has been deploying KS sensors in boreholes since 1974 at sites located all over the world and recently has begun installing Guralp CMG-3TB sensors at some sites. The Laboratory has

borehole experience on all seven continents ranging from tropical jungle in Brazil to the permafrost of Antarctica. At ASL, the personnel situation has remained relatively stable and there are several personnel with many years of experience working with boreholes – some have been at it for over 25 years.

Southern Methodist University (Dr Eugene T. Herrin, e-mail: herrin@passion.isem.smu.edu) has been active in the borehole field off and on over the years. Recently they have been quite active in developing innovative economical methods for installing broadband borehole arrays. As an organization, Sandia National Laboratories ([www.sandia.gov](http://www.sandia.gov)) has considerable experience in borehole technology, most notably with their Remote Seismic Telemetered Network (RSTN) program. However, the lack of continuity in their seismic program has resulted in the loss of many of the personnel with real field experience in borehole technology.

During the past 10 years, the IDA group at the Scripps Institution of Oceanography at the University of California, San Diego ([www-ida.ucsd.edu/public/home.nof.html](http://www-ida.ucsd.edu/public/home.nof.html)) has become involved in land-based borehole seismology as a part of the IRIS GSN program. They now have experience in drilling boreholes and deploying instruments at several sites around the world.

In conjunction with personnel from the Woods Hole Oceanographic Institute, Scripps is also leading the US effort aimed at developing pioneering borehole seismology techniques for use on the ocean floor. Independent programs in ocean bottom borehole seismology are also currently conducted by groups in France and Japan. Installing seismic sensors in the deep ocean is developing rapidly and we will not attempt to summarize practices in this field.

#### **7.4.6 Borehole strong-motion array installation (R. L. Nigbor, 2002)**

##### **7.4.6.1 Introduction**

*"An important factor in understanding and estimating local soil effects on ground motions and soil-structure interaction effects on structural response is the three dimensional nature of earthquake waves. ...For these purposes it is necessary to have available records of the motion at various points on the ground surface, along two mutually orthogonal directions, as well as at different depths."*

These words, published in the proceedings of the 1981 U.S. National Workshop on Strong-Motion Earthquake Instrumentation in Santa Barbara, California, are echoed in every important meeting where policies and priorities have been set regarding strong-motion monitoring. Earthquake engineers and seismologists alike agree: borehole strong-motion data continue to be a priority for better understanding of site response and soil-structure interaction issues.

This section is somewhat of a departure from much of the New Manual of Seismological Observatory Practice, as borehole strong-motion observations are primarily focused on site response and not on the seismic source or wave propagation path. For engineering purposes, borehole data in shallow (< 100 m) soils are of primary importance; these data are used to study amplification of earthquake shaking in the soil layers. However, borehole data in rock, especially weathered rock in the upper 30 m, are also important for the understanding of

strong ground shaking in earthquakes. Rock sites often show larger variability in measured ground motions than do soil sites. Examples of well-documented strong-motion borehole arrays are the EuroSeisTest Project (Riepl et al., 1998, and Fig. 7.65) and the Garner Valley Downhole Array (see Fig. 7.61). The user of this Manual should consult these references for further information about the details of borehole arrays and the use of borehole strong-motion data.

As important as borehole data are, many practitioners experience difficulty designing and constructing such arrays. As with the more traditional seismological borehole systems (see 7.4.5), strong-motion borehole arrays present a variety of challenges. Fortunately, much has been learned about borehole strong-motion instrumentation and vertical strong-motion array construction. In the past, borehole systems rarely survived more than two years. However, today there are many successful, long-term three-dimensional strong-motion arrays throughout the world. This accomplishment can be traced to better design, to new instrumentation, to better understanding of the historical failures, and to improved installation procedures.

This section is intended to assist with planning and implementing a successful borehole strong-motion array. Details of the instrumentation are not directly discussed but are available from the manufacturers of borehole strong-motion systems such as Kinemetrics (<http://www.kmi.com>). The sections that follow discuss borehole array planning, borehole preparation, geotechnical/geophysical measurements, installation procedure, and costs.

Fig. 7.61 shows representative borehole array data from the Garner Valley Downhole Array, Fig. 7.62 is a sketch of a typical, simple borehole strong-motion installation and Fig. 7.63 shows an example of a borehole strong-motion array. These sketches are meant to show the various components and terminology that will be discussed in this section.

**Fig. 7.61** Sample borehole strong-motion array data from Garner Valley downhole array

Fig.7.62 Sketch of borehole strong-motion accelerometer installation details.

Fig. 7.63 Sketch of a borehole strong-motion array.

#### 7.4.6.2 Borehole array planning

This section focuses on the planning issues related to borehole strong-motion array installation. The most important step in implementing a successful borehole accelerometer system is good planning. Done properly, by the time the borehole accelerometer package is actually lowered into the hole (as in Fig. 7.64 below), 95% of the effort will be complete. The following are important considerations:

- location;
- geologic implications;
- coupling and retrievability issues;
- sensor orientation;
- system issues.

##### ***Location***

Borehole data are needed for source mechanism and wave propagation arrays, local site effects arrays, and as free field input to structural response arrays. The location of the borehole is principally dictated by the needs of the particular project and thus the required array configuration. Borehole location and depth will also depend on the soils and depth to bedrock. It is recommended that external advice or review be obtained for borehole location selection.

**Fig. 7.64** Lowering a borehole accelerometer into the cased borehole.

Ground-borne noise is not the serious issue that it is with high-gain seismic systems, but it is still important to minimize non-earthquake vibrations in a borehole strong-motion installation. Few man-made signals will penetrate tens of meters of soil, so background noise will be reduced in a borehole sensor. However, some boreholes are shallow, and often the borehole accelerometer is collocated with a surface sensor. For this reason, the borehole should be located as far away from cultural (man-made) noise sources as possible. These include large, above ground structures, such as telephone poles, which can be driven by wind, vibration sources such as nearby rock quarries or industrial plants, and roadways bearing large vehicles.

The structure used for housing the recording station itself can be a source of coupled soil-structure vibration and must be designed carefully. The interaction of large structures with the soils can introduce noise into the ground motion. For this reason, the surface accelerometers should be located at least  $1.5H$  distance away from the structure, where  $H$  is the height of the structure.

Within an array of borehole and surface sensors, one must optimize the layout with regard to physical concerns such as cabling and environmental protection. The lengths of surface cables should be minimized for several reasons. First, because of cost. Second, the longer the cable the greater the potential for damage or introduction of noise or induced voltage, even if the cable is shielded and in conduit, and even if there is lightning protection both at the wellhead

box and at the recording station (as there should be). The recording station should be located near the wellhead boxes to minimize cable lengths.

Finally, it is best if the wellhead box is dry most of the time although it is assumed that the borehole itself is full of water and the wellhead box is designed to be waterproof. The top of the borehole should be positioned with regard to local water drainage and preferably not in a topographic low.

### ***Geologic implications***

Specific knowledge of the geology of a site is extremely useful during planning in order to meet project needs and accurately estimate the costs. The implications of local geology will depend upon the specific purpose of the borehole array. One should at least understand the surface geology, the depth to basement rock, and the local and regional tectonic structure. Fig. 7.65 shows a composite model of the EuroSeisTest site. This is an example of the kind of geologic understanding which should accompany a borehole strong-motion array installation.

The best information will come from both a thorough literature search to find existing information and then pre-installation geophysical studies. Once a site is selected, more detailed geophysical and geotechnical studies will be needed for ground motion and structural response modeling.

**Fig. 7.65** Geologic model of EuroSeisTest showing accelerometer array configuration.

### ***Coupling and retrievability issues***

The coupling of the borehole sensor to the surrounding soil is a critical issue for borehole strong-motion systems. The goal of the measurement is to record the particle motion of the native soil or rock at depth. Care must be taken to ensure that the borehole installation minimizes the disturbance of the soil or rock column. The borehole itself, the casing, the grout used to seal the casing and couple it to the surrounding soils, the borehole accelerometer package, and the method used to couple the package to the wall of the casing, all can have some effect on the recorded motions, especially if the motions approach 1g. The issue of coupling is related to instrument retrievability, which is the ability to pull out a borehole sensor if repair is needed. For some borehole sensor installations, a permanent coupling solution (grouting or cementing the sensor in place ) may be selected. This is not recommended as experience has shown that borehole sensor failure does occur. Failure of a borehole sensor that can not be retrieved not only entails the replacement of the sensor, but of the borehole as well, and the cost of the borehole often well exceeds that of the instrumentation.

If permanent coupling of the sensor is essential, using some sort of grout, it is advisable to design the borehole system to have a “weak point” above the sensor that will break cleanly when the cable is pulled and leave as little of the cable as is possible in the hole. If the sensor fails, it would be possible to abandon the sensor and cement in a replacement in the same borehole at a slightly shallower depth.

Removable coupling (locking) methods include backfilling the annular space around the package with some specified material, wedge-type locking systems, and pneumatic/hydraulic locking systems. Backfill materials used in the past have included sand, gravel, lead shot, and glass beads. Of these, water saturated sands can be expected to liquefy under vibrating conditions, and lead shot has been found to cold form over time, making retrieval difficult and even impossible. This leaves gravel or glass beads as successful alternatives. Kinemetrics recommends the use of a combination of 3mm and 5mm glass spheres as a coupling method; the company can be contacted for further details.

Several commercial wedge-type locking systems are available from borehole sensor manufacturers. Experience has shown that these will work well in shallower (<50m) installations, but may become unreliable in deeper installations. Some borehole installations, such as the 500m borehole sensor installation at the Garner Valley Downhole Array have used custom hydraulic locking systems. Some temporary borehole strong-motion sensor installations have used pneumatic (air-pressure) locking systems with success, but the air pressure must be maintained.

### ***Sensor orientation***

Another important issue in borehole strong-motion studies is the accurate orientation of the horizontal components of the borehole sensors. In the past, practitioners have most often relied on loading poles to manually orient the instrument package. Loading poles are generally square-section tubes which are rigidly attached to the accelerometer package. During installation, the loading poles are joined end-to-end with the painted side facing the same direction as the others, thereby permitting the package to be manually oriented from the top of the hole. This manual method can work well for shallow (< 20 m) borehole installations, but twisting of the poles can introduce large errors for deeper installations.

Fluxgate magnetometer sensors were first used with strong-motion borehole instrumentation in the late 1980's by a firm called Applied Geophysics of Los Angeles. At that time, the compass was used to determine the arbitrary orientation of a slotted end cap installed at the bottom of the PVC casing by the driller. The mating notch on a special borehole package was then rotated and fixed so that, once guided (by gravity) into position in the slot of the cap, the package was oriented as desired. This method was expensive because of the special construction and installation of the cap at the bottom of the hole, and the special packaging required to accommodate the orientation notch.

The current generation of commercial downhole accelerometers (for example, Kinemetrics FBA-23DH) have provisions for an internal fluxgate magnetometer compass to make orientation simpler and much less expensive than either loading poles or borehole bottom devices. With this device, one simply observes the compass orientation via a notebook computer at the surface and rotates the sensor cable until the correct orientation is achieved. Accuracies of 2-3 degrees can be achieved with this method.

It is also possible to simply install a downhole accelerometer with random orientation and then to determine the orientation later by comparing the vector orientation of a surface sensor to that recorded from the borehole sensors. Orientation can be determined after installation by comparing surface and downhole data, either earthquake or microtremor. Note that anisotropy in the near surface soils can produce errors in this type of orientation unless the events are large regional events with significant long-period energy, i.e., with wavelengths much larger

than the soil depths. Using a known source location, the orientations can be determined to  $\pm 5^\circ$  by using linearity of 1<sup>st</sup> motions on radial and transverse components (see Aster and Shearer, 1991).

### ***System issues***

The borehole accelerometer package can not be installed properly without consideration of the overall system, and particularly the recording device. Usually, the recording system will have exceptional dynamic range to take advantage of the low noise qualities of the borehole installation and the accelerometer. Therefore, particular care must be taken avoid system-related noise due to improper grounding and other common problems. Additional issues include system level lightning protection to protect circuitry against large voltage transients. Many of these system issues have been discussed in detail in 7.4.2.1.

### **7.4.6.3 Borehole preparation**

A critical step in a successful borehole accelerometer installation is the preparation of the borehole itself. The borehole should be vertical, carefully drilled, with carefully installed casing grouted to ensure good coupling of ground motions at higher frequencies. Fig. 7.66 shows a typical drilling site. One can see that this can be a major construction effort.

### ***Planning***

Site selection for borehole accelerometers is often dictated by factors other than practicality for drilling operations. If there is room for adjustment of borehole location, try to meet or exceed the following minimum clearance requirements:

- 2m from borehole to any obstructions such as fences, walls, or ditches;
- two 10m paths 4m wide on opposite sides of the borehole for drilling equipment;
- no overhead power lines

Access to the site should be able to support repeated trips with heavy trucks without damage. If a site is located in soft soils, consider the use of wood under the wheels of the drill rig and a four-wheel-drive water truck. Some sites may require the use of track-mounted drill rigs for access, or heavy earthmoving equipment to help position the drill rig on site. Fig. 7.67 below demonstrates why these are requirements for a drilling operation. Important steps in borehole preparation are planning, contractor selection, permitting, drilling, sampling, casing, and grouting. These issues are discussed below.

**Fig. 7.66** Typical borehole drilling operation in an open area.

**Fig. 7.67** Drilling operation in a confined area, showing size of drill rig.

Water availability is critical for drilling operations. A residential-type supply is adequate as long as an on-site water tank or truck is available to provide storage for peak demands. If all water is to be supplied by truck, a water supply capable of filling the truck quickly should be located within a 15 minute drive. Disposal of drill tailings and excess water is usually not a problem in remote sites where the tailings can be spread around the surrounding area to dry. In urban areas, fluids can be channeled sometimes down drains or ditches, but solid tailings must be removed. For shallow holes this can be done in drums and a pickup truck, if a nearby spot can be located to dispose of the tailings. In urban areas, a separation cone can be placed over a waterproof dumpster, and tailings collected in the dumpster, to be removed periodically by a liquid waste hauler with a vacuum-lift truck. In some areas, drill tailings are automatically classified as hazardous waste, which complicates disposal matters tremendously. Be sure to work these issues out before starting the project. In many developed areas, this can be a large cost item, easily as large as the drilling costs.

If multiple boreholes are to be drilled in one location, a separation of 6m between boreholes is generally adequate to prevent damage to a borehole during the drilling of subsequent boreholes. This should preclude the possibility of boreholes drifting laterally into each other during drilling. Shallow holes may be placed closer together by drilling in a line and backing the drill rig over the most-recently completed hole to protect it from damage.

The time of year chosen to begin a drilling project may significantly affect the schedule and cost of a project. Warmer weather is generally desirable, as are long periods of daylight and a lack of rain or snow.

### ***Selection of drilling contractor***

The selection of a drilling contractor must be based upon a number of factors; perhaps the least important of these is cost. If geotechnical sampling is to be performed, the contractor must have the equipment and crews familiar with geotechnical drilling practices. The key item in drilling is experience with the tasks to be performed and the equipment to be used. Drilling deeper (>50m) boreholes is not the place to have an inexperienced crew. The driller's reputation for completion of work and quality of work should be reviewed. It is strongly recommended that one obtain references for a drilling contractor.

When obtaining a bid, consider getting separate bids for a fixed price per meter and for actual time and materials used. For deep boreholes, fixed price per meter bids may appear more expensive but can save enormous amounts of money if a site is difficult. In addition, most companies will send out their best crews on fixed price bids, generally giving faster completion and fewer complications. In the long run, fixed price contracts often save money.

### ***Permits***

The drilling of boreholes near aquifers is carefully controlled in many countries to ensure that ground water sources are not contaminated. This control is generally exercised by local government, often through environmental health departments. Usually the responsible entity will require the submission of a permit application detailing depth, diameter, location, property lines, adjacent structures, wells and septic systems; well construction method, owner, and licensed driller to perform the work, and a fee of several hundred dollars per well. The application may require the signature of the land owner and the drilling contractor. In addition, some regions require copies of the driller's license and a performance bond before the driller is approved for work. In the US, typical permitting work is as follows:

- submission of permit application and fee;
- after permit application and payment of fee an inspector will usually visit the site before issuing approval of the permit;
- during construction, depending upon location, the inspector may visit the site several times, and may require notification 24 hours before grout is to be placed;
- in some municipalities, an inspector must be present during the grouting process;
- notifying the permitting agency of the completion of wells; usually this is in the form of a drill log which shows lithologic information and details of the well construction.

In other countries, and in rural or remote areas, permitting may not be needed. However, permission by the owner of the land will likely be required in all cases.

### ***Drilling***

There are several methods for shallow drilling in soils and rock. The book by Driscoll (1986) on Groundwater and Wells is a good reference for the various methods. Several ASTM (American Society for Testing and Materials) Standards describe drilling methods as well (see <http://www.astm.org>). A good start is ASTM D420-98 "Guide to Site Characterization for Engineering, Design, and Construction Purposes."

Direct rotary or "rotary mud" drilling is the drilling methodology best suited to most downhole accelerometer installation projects. One major advantage of this method is the support that the borehole wall receives from the drilling fluid that always fills the borehole. This method can be performed in both hard and soft formations, and can be done using fairly compact equipment. The drilling is performed by rotating a bit on the end of a heavy pipe or "drill string", which is driven down by its own weight, or by additional downward forces applied by hydraulic cylinders or chain pull-downs on the drill rig. The bit is lubricated, and drill cuttings are removed by drilling fluid or "mud" that is pumped down to the bit through the drill string. The fluid then returns to the surface through the annulus formed by the outer surface of the drill string and the borehole wall. This is possible because the borehole diameter is generally several inches larger in diameter than the drill string. As the fluid moves to the surface it carries with it the particulate debris produced by the cutting action of the bit. At the surface the fluid is directed into a holding area, either a box or dug pit, to let the cuttings settle out before the fluid is pumped down the drill string again.

Speed of completion is important in drilling due to the potential loss of a borehole by collapse. Some soil formations will remain open for long periods of time even if the fluid level drops significantly; other formations will cave in with the slightest provocation, even when filled with thick drilling fluid. In many instances, the premium paid to work around the clock is justified by the savings of not having to remove the drill string each evening, and the reduced risk of borehole collapse during the night.

Drilling is a messy business due to the large volume of water and mud involved. In a confined urban space such as an alley, a 100 m borehole might be drilled by a truck mounted rig only 8 m long, with an 8m tall tower, with only 1m of clearance on either side of the rig. Water and drill rod would be transported by a single 6m truck. All cuttings could be contained and removed from the site in 200 liter drums or a larger container. This would be possible but is far from an ideal situation. In a rural or remote area, a 250 m borehole might use a rig 15 m long, with a tower of 10-15 m, a separate pumping rig 10 m long, a 12 m drill string trailer, a

water storage tank, a mud pit 3 by 6 m, and an area several hundred m<sup>2</sup> to hold cuttings piles and miscellaneous support equipment. Fig. 7.67 shows such a setup.

Installation of a typical 100 mm (4 inch Schedule 40 or 80) PVC casing requires a minimum 200 mm (8 inch) diameter borehole. A larger diameter may be used when needed to maintain a clear hole, but this will increase drilling and grout costs and the potential of damage to the casing from grout cure heat, discussed further in the section on grouting. Most municipalities in the USA require a 50 mm (2 inch) annular seal around the casing, and this diameter meets this requirement. Depending upon the size of the drill rig used, this may be drilled in one pass, or a smaller pilot hole; usually 120 mm (4 7/8 inch) diameter will be drilled first, and all sampling and geophysical testing will be done in the pilot hole before drilling again to the final size.

There is a trade-off between speed of drilling and verticality of the borehole. Since verticality is an important issue for downhole sensor installations, it is important to make the driller aware of this, and stress that slow steady drill rates and perhaps collars attached to the drill string can help keep the borehole vertical. If you can get the driller to agree to a tolerance when doing a contract, this will also help keep the drill rig operator focused on this issue. Deviations of less than 5° from the vertical are acceptable. Larger deviations will affect the dynamic range of most sensors, unless the instrument has some type of auto-leveling device.

### ***Geotechnical sampling***

Generally, installation of a downhole accelerometer, or vertical array, is done to understand the effects of local site response on ground motion. Acquisition of soil or rock formation samples during drilling, as well as geophysical information, provide a great deal of information useful in site characterization studies. Not only can these samples provide clear indications of the formations beneath a site, but can also be used in laboratory studies to determine structural characteristics of the formation.

Soil sampling is described by Kenji Ishihara (1996) and by Driscoll (1986). Several ASTM standards also exist for sampling; two important references are ASTM D1586-99 “Standard Test Method for Penetration Test and Split-Barrel Sampling of Soils” and ASTM D1587-94 “Standard Practice for Thin-Walled Tube Geotechnical Sampling of Soils”, both from <http://www.astm.org>.

In general, one will use five major categories of sample types in borehole strong-motion array studies, as discussed below.

- **Bag samples** are simply a collection of drill cuttings carried to the surface by the drilling fluid and caught as they enter the mud box or pit. The accuracy of this sampling method is influenced by a number of factors including depth of the borehole, rate of circulation of drilling fluid, and size of cutting fragments produced by the drilling process. This method has limitations, due to the introduction of clays from the drilling fluid into the sample, as well as older material falling off the borehole wall. However, when used in conjunction with a detailed record of drilling rate, bag samples can provide extensive information about formation.
- **Drive sampling** (“Split-Barrel Sampling” or “SPT” sampling) produces an intact but disturbed sample 2.5-5 cm (1-2 inch) in diameter by driving a sample tube into the formation at the bottom of the borehole. This is done by removing the drill string and

lowering the sample tube, mounted on the bottom of a sliding hammer, to the bottom on a cable. The hammer is then actuated by lifting and dropping the cable until the sample tube has been advanced the desired distance. Often the number of blows to advance a given distance is recorded to provide blow count (SPT N-value), a measure of formation hardness. This procedure is time consuming because it requires the removal of the entire drill string from the borehole, but provides samples with excellent depth control. This method is useful only in soils. Fig. 7.68 shows typical drive samples.

**Fig. 7.68** Drive samples being collected for later laboratory testing.

**Pitcher samples** (“thin-walled tube” samples) produce an undisturbed sample 75 mm (3 inches) in diameter and up to 750 mm (30 inches) long. This technique is used when large high quality samples are required for laboratory tests, and where formations are too hard to yield results with a drive sampler. Pitcher sampling is performed by removing the drill string from the borehole and replacing the standard bit with a pitcher sample barrel. The barrel supports a thin wall steel tube on a spring loaded plunger. The plunger allows the tube to retract through the center of an annular carbide bit when it reaches the bottom of the borehole. Drilling then proceeds, cutting an annulus. The 75 mm (3 inch) center core is forced into the thin wall tube. When advancement is complete, the entire assembly is removed and the core shears off at the bottom of the thin wall core tube. The sample may then be stored and transported in the tube, or extruded at the drill site. The original bit is then replaced and lowered to the bottom of the borehole to resume drilling. This is a very time consuming procedure, as it requires removing and inserting the entire drill string twice, but it yields very good undisturbed soil samples. This method is not used in very stiff soils or rock. Fig. 7.69 shows some Pitcher samples in the field.

**Fig. 7.69** Pitcher samples.

- **Diamond core samples** are taken in hard formations, usually rock. The procedure for diamond coring is identical to Pitcher sampling, except that a diamond core barrel is used. It also cuts an annulus while retaining the center core inside the core barrel. As with the Pitcher sample, this is a very time consuming procedure, as it requires removing and inserting the entire drill string twice, but is the only way to obtain samples in hard rock. Continuous coring provides a complete undisturbed record of the formations the borehole passes through. There are several ways of performing continuous coring; one method is referred to as “wireline” sampling. This, as well as most continuous methodologies, allow for the mounting of a variety of annular bits at the bottom of the drill string as well as for the exchange of the center portion of the bit from cutter to sample tube via a lightweight wireline cable through the center of the drill string. This permits the retrieval of cores without removing the drill string. This is a superior methodology for deep (>200m) boreholes where the larger drill rigs required to support it are justified.

### ***Casing***

A plastic (PVC, poly-vinyl-chloride) cased borehole is recommended for installations to 250 m depth. Medium-walled casing (“Schedule 40” in US standards) is acceptable to about 50 m depth; thick-walled (“Schedule 80”) should be used for installations between 50 and 250 m. Steel casing is recommended for deeper installations. As discussed elsewhere in this Manual, the Kinometrics FBA-23DH and its associated installation equipment are designed for use with Schedule 40 PVC casing. The bottom of the casing is closed with a slip cap. In the United States, this casing is typically supplied in 20 foot lengths with “bell-end” sockets molded at one end to receive the straight “spigot” end of the next casing section. Other sizes and forms of casing may be used but will require modification of associated installation items. Magnetic casing materials must not be used in conjunction with the flux-gate magnetometer compass option.

Joining of PVC casing sections is done using a solvent glue. A primer is used to clean and etch the surfaces to be joined before the glue is applied. Low temperatures can significantly degrade the quality of a solvent joint, as can the presence of water on the joint surfaces. If temperatures are below 0 degrees C, a low temperature solvent glue should be used. More expensive screw-joint casing can be used as an alternative.

Installation of the casing, except in the shallowest holes, requires filling the casing with water, sometimes drilling fluid, to negate the buoyancy of the casing column thus allowing the casing to be pushed down into the fluid filled borehole, usually by hand. In addition, fluid inside the casing equalizes internal and external pressures, preventing the collapse of the casing due to external fluid pressure in deep boreholes (greater than 100 m).

Attempting to push empty casing into a fluid filled borehole with the weight of the drill rig causes casing to "snake" in the borehole, making accelerometer installation more difficult, as well as increasing the risk of damage to the top of the casing section being forced down or by telescoping an uncured glued joint.

Joining PVC casing by the use of screws in conjunction with gluing is not recommended, due to the potential for protrusion through the interior wall and subsequent damage to the cable during installation, as well as providing a path for leakage of water out of the casing following installation. If screws are used, only stainless steel screws set partially through the casing should be used. Pilot holes should be drilled in the casing after gluing to prevent fracturing of the casing during screw emplacement.

### ***Grouting***

Grouting the well casing involves filling the annular space between the casing and the borehole wall with a suitable slurry of cement or clay. For borehole accelerometer installations it is critical that this process is done with care, to ensure that the casing is well-coupled to the native soil or rock.

The grout is pumped into place through a small diameter pipe, usually a 25mm (1 inch) galvanized steel called a "tremie tube", lowered into the borehole between the casing and the borehole wall. When the end of the pipe reaches the bottom of the borehole, drilling fluid is circulated through the tremie tube to establish a clear path for the grout, and to clean the bottom of the borehole of any settled material. The grout is then pumped down to the bottom of the borehole, where it displaces drilling fluid out of the top of the borehole. The pumping may be done by the pump on the drill rig, or by a separate grout or concrete pump. When the drilling fluid is completely displaced and grout is flowing from the top of the borehole, the pump is stopped and the tremie tube withdrawn, disassembled and cleaned. Many U.S. municipalities require that the volume of grout placed be recorded and that it meet or exceed the volume calculated for the annulus. In some deep boreholes, grout will be placed in several separate loads or "lifts" to reduce the pressure exerted on the pipe by the liquid grout, as discussed later. This is usually scheduled as one lift per day.

Local codes usually require a sanitary seal of cement grout in the top 15m of a well, and seals between all aquifers penetrated by the well. The other areas may be filled with sand or gravel, but it is generally cheaper just to fill the entire annular space with cement grout. This will also make the eventual abandonment of the well (which can require another permit) much simpler.

Common grouting practices primarily center on the use of cement and water ("neat cement"), although the slurry may also contain sand, bentonite clay, or hydrated lime in certain

situations. For downhole installations a mix of 400kg (20 U.S. sacks) of Portland cement type A or B per cubic meter of grout works well. Addition of 5kg of bentonite clay per cubic yard will ease the pumping of the grout into deep boreholes.

It is important to recognize that cement grouts exert greater collapse pressure on casing than water or drilling fluid. Installing grout 60m at a time for Schedule 40 PVC pipe provides a safety margin against casing collapse for the added effect of softening of the pipe by the heat of cure of the grout.

Other methods of placing grout, for example through a one-way valve in the bottom of the casing, are sometimes used but are generally considered to be less reliable. Be sure that the drilling contractor is completely comfortable with whatever method is to be used.

#### **7.4.6.4 Geotechnical/Geophysical measurements**

The primary motivation for installing downhole accelerometers is to increase understanding of the contribution of site response to the earthquake ground motion. Often the measurements of site response will be accompanied by analytical studies. Detailed understanding of the subsurface geology and soil/rock properties is necessary for such analytical studies. A good example of the kinds of site characterization data needed for strong-motion site response studies can be found in the documentation of the project

“Resolution of Site Response Issues in the Northridge Earthquake – ROSRINE” (<http://peer.berkeley.edu/news/2001spring/rosrine.html>).

The basic site geology provides the primary description of the site. Information obtained during drilling (through observation and soil sample collection) will augment any prior geological knowledge of the general area. Normal laboratory testing of soil samples (disturbed or undisturbed) will confirm soil/rock types. Borehole and surface geophysical measurements can also assist in determination of site geology.

In addition to the site geology, dynamic soil and rock properties are needed for modeling of earthquake site response. The primary modeling properties are density, dynamic modulus, and damping (Q-value). The latter two properties are nonlinear functions of strain. These properties are obtained by laboratory testing of undisturbed samples and by one or more surface or borehole geophysical measurements of shear-wave velocity.

This Chapter gives a brief overview of the most common geological and geophysical measurements used in conjunction with borehole accelerometer installations to determine site geology and dynamic soil/rock properties.

#### ***Literature search***

In most populated areas there will have been previous geological studies of the region and perhaps even local environmental, ground water, or planning studies. These can contain a wealth of information that will assist in site response studies. Planning for a borehole accelerometer installation should include a thorough literature search for such previous studies.

Potential sources of information on a regional basis are government geological or natural resources agencies. An example is the U.S. Geological Survey. For local studies, sources of

information are the local government planning agency, local universities, private water companies, and even local water well drilling companies. A literature search can be a very inexpensive source of information on site geology and even subsurface soil and rock properties.

### ***Pre-installation geophysical studies***

Before site selection and borehole drilling, geophysical methods can be used to obtain a more detailed understanding of the site geology and subsurface properties. A good review of methods for site characterization is found in ASTM Standard D420-98 “Guide to Site Characterization for Engineering, Design, and Construction Purposes” and in ASTM Standard D6429-99 “Standard Guide for Selecting Surface Geophysical Methods” (see <http://www.astm.org>). For borehole strong-motion array applications, common methods are:

- seismic reflection;
- seismic refraction;
- resistivity profiling;
- cone penetrometer.

Seismic reflection and refraction are two techniques for using surface measurements to determine the seismic wave velocity structure of the subsurface geology. Both use a surface source of energy (mechanical or explosive) and instrumentation for measuring travel times of seismic waves at various distances from the source. Inverse analysis of these travel times provides an estimate of the seismic wave velocities of soil and rock layers. These methods can provide a cost-effective determination of general soil/rock layer properties, bedrock depth, and water table depth over a wide area.

Resistivity profiling is another surface technique for measuring the electrical properties of the subsurface geology. The electrical field from a surface AC or DC current source is measured at several locations. Inverse analysis is then used to estimate the resistivity of the subsurface soil or rock. This method can assist in both shallow (< 100 m) or deep (> 100 m) geological studies of a site.

The previous methods have all been noninvasive surface techniques. Initial geological studies of a potential borehole accelerometer site can also include the invasive techniques of cone penetrometer studies. These allow detailed soil/rock type determination at a specific location. A cone penetrometer (a metal probe pushed into the soil) can also obtain information about shallow (< 30 m) soils. Exploratory drilling can also be used in these initial site characterization studies.

### ***Lithology logging***

An experienced geologist should be present during drilling to determine the soil and rock classification. This is done by observing the drill cuttings, the samples, and the action of the drill rig. A good procedure for such lithology logging exists in the ASTM Standard D5434-97 “Standard Guide for Field Logging of Subsurface Explorations of Soil and Rock” (see <http://www.astm.org>).

### ***Laboratory testing of soil samples***

Samples obtained during drilling are useful in determining the soil type and soil properties. Basic geotechnical soil properties can be determined by simple laboratory testing, including:

- moisture content;
- dry density;
- LL/PL; and
- void ratio (porosity).

These simple soil measurements can be performed by most commercial or university soil laboratories.

Dynamic laboratory testing, however, requires a much more skilled and specialized laboratory and very high quality undisturbed samples. Dynamic properties of primary interest for earthquake site response analysis are soil shear modulus and material damping ratio (in shear) and their variations with:

- shear strain;
- effective confining pressure;
- loading frequency;
- loading duration; and
- number of load cycles.

Dynamic testing should be performed using triaxial resonant column, simple shear, or torsional shear methods. Appropriate strain ranges for earthquake response studies are 0.0001% to 0.1%. Appropriate frequency ranges are <1Hz to 200Hz. Further details of dynamic testing can be found in the book *Soil Behaviour in Earthquake Geotechnics* by Ishihara (1996) and other textbooks on soil dynamics.

### ***Borehole geophysical measurements***

There are many geophysical measurements available for characterization of the soil and rock properties in a borehole. These can measure chemical, electrical, radiation, and mechanical properties. All require specialized instrumentation and a skilled, experienced field geophysicist.

The chemical, electrical, and radiation properties are generally not of interest in an earthquake site response study, except as they are useful in determining soil and rock types. Sometimes resistivity and natural gamma emission measurements in an uncased borehole (before installing PVC casing) can be useful in determining boundaries of clay, sand, and rock layers

Of particular interest to site response studies are the mechanical properties of the soil and rock, primarily the P-wave and S-wave velocities versus depth (velocity profile). Borehole methods for velocity profile measurement are:

- downhole (vertical seismic profiling);
- crosshole; and
- suspension.

All three methods use a mechanical or electromechanical source to produce seismic waves, and one or more sensors (generally geophones) and a recording system to measure the induced ground motion. Details of these methods can be found in the book by Kenji Ishihara (1996).

For the downhole test, an impulsive energy source at the surface near the borehole top produces seismic waves which propagate radially. These can be either P waves or SH waves, depending upon source configuration. One or more sensors are installed in the borehole at known depths. The source and sensor signals are recorded, and the travel time of the first wave arrival is measured as a function of depth. The instantaneous slope of the travel time vs. depth curve is the reciprocal of the wave velocity at that depth.

**Fig.7.70** Velocity profiles for P waves (red curve) and S waves (blue curve) at a strong-motion site.

The crosshole test requires two or three adjacent boreholes separated by known distances. A source is installed in one borehole and receivers in the others, all at the same depth. The travel time of the generated seismic waves between boreholes is measured, and the velocity calculated by dividing the separation distance (at depth) by the travel time. This method requires careful control over the source and receiver depths, and detailed measurement of borehole separation versus depth. Both the downhole and crosshole methods are normally performed in cased boreholes. The suspension method, however, can be used in either cased or uncased boreholes. It consists of a single probe about 5 meters long, with an impulsive source at the bottom and two sensor sets ("receivers") near the top, separated by 1 meter. The source transmits energy through the borehole fluid to the borehole wall where it is transformed into both P and S waves. These are detected by both receivers, and the difference in arrival times is measured. Dividing the 1 meter separation by the travel time differences gives the P- and S-wave velocities for the 1 meter interval between sensors. Fig. 7.70 is a plot of a velocity profile measured with the suspension method.

#### **7.4.6.5 Installation procedure**

Depending on the goals and the operational environment of strong-motion installations there exist different guidelines for site selection, instrumentation and installation, e.g., those published by the Consortium of Organizations for Strong Motion Observations Systems (COSMOS) for urban or advanced national seismic strong-motion reference stations. These guidelines are available via <http://www.cosmos-eq.org/publications>. This section describes the careful installation of a downhole strong-motion sensor, its orientation, operational checkout, evaluation period, coupling/locking, and documentation/reporting. Accompanying this procedure will be a procedure for the installation of surface sensors, surface cabling, recording station, and other infrastructure, which have been discussed in more detail in earlier sections of 7.4.

##### ***Sensor installation***

After completing functional tests of the sensor, the wellhead box, the cables and recorders, and calibrating the internal compass, the borehole package can be installed. The following procedure assumes a standard installation of a Kinemetrics FBA-23DH sensor with glass beads or gravel, and the internal compass for orientation. Installation for other downhole strong-motion sensors will be similar.

If not already done, the borehole should be filled with clean water to within 6m of the top. Filling completely will make installation easier since the water gives the cable near- neutral buoyancy, allowing a single person to handle the weight. In any case, consideration must be given as to where the displaced excess water will go when the package and cable are lowered into the hole.

This is the main reason a drain should be provided for the wellhead box, even though it is sealed from weather, and also why sufficient slack surface cable should be provided in the wellhead box to allow the contents of the wellhead box to be temporarily moved out of the way. In a sealed system, it would be best if the drain were sealed off after performing this function, to prevent moisture from entering the wellhead box after installation is complete. If the borehole has already been checked, the package can be lowered smoothly using the cable, being careful not to allow the cable to slip away. Fig. 7.64 shows this procedure in action. It is good practice to have a second person feeding the cable to the person lowering the package.

If the borehole has not been checked previously, care should be taken to "feel" for any constrictions in the casing which could signal trapping of the package. If such is felt, it is wise to move slowly, and then try coming back up every meter or so until the obstruction is passed. Check the total depth of installation by using the depth markers provided on the borehole cable (if available). Continue until the sensor is resting on the bottom of the borehole.

### ***Orientation***

This procedure assumes an internal compass in the sensor package. Once the sensor package has reached the bottom of the casing, apply power to the compass and rotate the package using the cable until the desired orientation is reached. Feed slack cable into the casing to help hold the sensor in position. Allow the package to rest on the bottom to get a steady reading, and measure the accelerometer offsets. Record the offsets carefully.

The acceptable DC offset depends on the final gains expected to be used with the system. If possible, it is desirable to keep the offsets to less than 25 millivolts. To accomplish this, compensating offsets will usually need to be applied to counteract the combination of residual factory offsets and vertical misalignment of the casing at the bottom of the borehole. In other words, if an offset of +150 millivolts is recorded for the horizontal sensor oriented east at the bottom of the hole, then when the package is removed to the top, the offset for the same sensor must be mechanically adjusted so that -150 millivolts is added to whatever the offset is before the adjustment. This must be done carefully so that the package orientation doesn't change from the beginning of the adjustment to the end. This is where some sort of test fixture is helpful to hold the package steady. This procedure may need to be repeated in order to get it right. In fact, expect to repeat this procedure once more after 30 or 60 days of operation before installing the backfill material, after the sensor has adjusted completely to the temperature at the bottom of the borehole. This requires opening the sensor package which can be difficult in field situations. Requiring the driller to produce a vertical borehole within a predetermined tolerance can often avoid this.

### ***Operational checkout***

Once the package has been installed and oriented with acceptable DC sensor offsets, one should connect the recording system and check for proper sensor operation. This operational checkout should follow manufacturer's procedures, and results of the system test should be compared with the factory reference test.

### ***Evaluation period***

It is recommended that the array be operated for at least 30 days and as much as 60 days prior to installation of the backfill material. This period is needed to eliminate any initial startup problems, and allow the sensors to achieve steady state temperature response. During this period, the sensor package will rest at the bottom of the borehole. While this is inadequate coupling for large earthquakes, it should prove adequate for small events.

Preamplifier gains in the recording system should be set 10 to 100 times higher than normal in order to record as many small events as possible during this initial test period. Data should be reviewed, and the sensor removed and checked if any problems or questions arise.

### ***Coupling/Locking***

Once the downhole accelerometer has functioned properly for a period of 30 to 60 days, it is time for installation of the coupling or locking device. If a permanent locking method (i.e., grout or cement) is to be used, one should carefully install the locking material without disturbing the sensor orientation. If a wedge-type, pneumatic, or hydraulic locking system is used, it should be tightened to final specifications. If sand, gravel, or glass bead backfill is used, proceed with backfilling. Resist the temptation to pull on the cable afterwards to confirm the security of the system. It is possible to shift the package enough to disturb the orientation, and not be able to get it right without pulling it out, or you could lose backfill material to the bottom of the borehole. It is better to trust the process, and assume the material is in position. The proof is in the results.

### ***Documentation/Reporting***

Excellent documentation is very important to preserve the details of construction and installation for better interpretation of the data. Most important is the proper organization and use of calibration data. It is suggested that a formal Commissioning Report be created to preserve this installation information. Photographic documentation is also important. All documentation should be preserved along with the data for use in future data analyses.

### **7.4.6.6 Costs**

A borehole strong-motion array can be quite expensive when all the needed work is considered. Besides the cost of instrumentation, there are the planning, preparation, site studies and installation costs. One could omit some of the planning and site characterization costs (this is often done), but at a significant cost in understanding of the resulting strong-motion data.

Costs will vary considerably in different parts of the world. With this proviso, below is a commercial cost estimate for a representative borehole strong-motion array with one borehole at 100 m depth and one surface sensor. The year 2000 costs in US\$ in the U.S./California are:

- Instrumentation (one borehole accelerometer, one surface accelerometer, one 6-channel seismograph) - \$20,000;
- Downhole sensor cable - \$4,000;
- Array infrastructure (power, enclosures, communications, etc) - \$10,000 ;
- Planning and initial studies (includes one seismic refraction line) - \$10,000;
- Borehole preparation - \$15,000;
- Geotechnical/Geophysical Studies (includes lab testing of soils) - \$15,000;
- Array construction and installation - \$10,000;

**TOTAL COST = \$84,000.**

## **7.5 Marine seismic observation (M. Shinohara, K. Suyehiro, and H. Shiobara, 2011)**

### **7.5.1 Deep ocean environment, required logistics, sensors and data recording**

#### **7.5.1.1 Introduction**

In this section, we describe the logistical, legal, environmental and technical requirements and conditions to be considered and met by an observer who attempts to acquire seismic data from the sea floor. Currently, most of earthquakes with magnitude ( $M$ )  $> 4.5$  can be detected anywhere in the world including the oceans (e. g., <http://earthquake.usgs.gov/>). Satellite altimetry data show us the large-scale seafloor topography (bathymetry) of tectonic features such as the oceanic ridges, trenches, and transform faults, which can be compared with global seismicity. Based on these general pictures, an observer can design seismic experiments to look into the heterogeneous structures of different tectonic provinces or locate and analyze background microearthquakes or aftershock sequences in the wake of major off-shore earthquakes, and so forth. We are motivated to use marine observations by the inhomogeneous distribution of land-based stations and insufficient azimuthal coverage of seismic sources and structural-tectonic features to be investigated. Such data resolve systematic biases in derived parameters and models better than data from only land-based seismic observations. Because the oceanic plates recycle through the Earth's crust and mantle through time, there are many fundamental problems to be studied. There are often important gains and it is sometimes necessary to make specific observations on the seafloor rather than from land, or in combination with land-based seismic networks. Examples of gains from including seafloor observations include: achievement of more complete azimuthal coverage, higher spatial resolution and accuracy in earthquake locations and in source mechanisms studies, and in tomographic velocity or attenuation models. Seafloor

observations avoid contamination or complications from data sampled over too large a distance and across major heterogeneities.

#### **7.5.1.2 Access**

For research purposes, most Ocean Bottom Seismograph (OBS) operations are temporary operations spanning from several to a few hundred days across a spatial scale from 10 to 1000-km. To work in the marine environment, one must first be able to bring the OBSs to the desired locations, then install them there, and to recover them after the mission is finished. This is done by ocean going vessels. Dropping OBSs from a helicopter has been done but recovery requires a boat. If the instrument needs to be positioned at a precise location or requires a special installation scheme such as burying the OBS, one needs extra methods such as utilizing an ROV (remotely operated vehicle) to reach the seafloor or a submersible with robotic functions.

##### ***The ship***

Depending on the size and the weight of each OBS, the maximum number of OBSs that can be put on board will be restricted. Experiments close enough to shore that the transit time is short may use a smaller boat and deploy groups of instruments during several short cruises. The availability of a ship is an important condition. Ships may be obtained either through application to organizations managing research vessel operations, by open competition through a proposal review system or if you have your own funding, by charter of a commercial vessel. Usually a management body will do the scheduling of the ship and one will need to adjust one's schedule to fit the ship schedule. In the case of a chartered vessel, one may have more control, but the ship's capabilities must be carefully looked at in the light of requirements and costs.

The ship must have the capacity to store all the OBSs away from severe vibration and temperature changes that could affect the seismograph system performance. Recently, we have sought to keep onboard work to a minimum and to keep the instruments inside their pressure housings. The instruments can be calibrated by using a calibration coil or applying an electronic test pulse (see Chapter 5, sub-chapter 5.6), and the stored data read without opening the cases. However, there could be situations where one needs to refurbish OBSs, so one needs a clean and dry lab with appropriate space and access to the deck. Such a lab could be a container lab that can be brought to ship for the experiment.

Active controlled source OBS experiments using an airgun array and hydrophone streamer to simultaneously monitor the reflected seismic waves require a ship's crew trained in this type of operation, and a vessel able to run in a straight line at a constant speed across the ground. Such methods are common in the oil industry, but less common in the academic research world. Details will not be given here, but in general, there is the mechanical system to tow the airguns and the streamer, a pneumatic system with an air compressor system sufficiently powerful to shoot the airguns at the desired pressure (100-150 kg/cm<sup>2</sup>), and repetition rate (10s of seconds), an electrical system to control the shooting sequence and to log the sequence and to record the data from the streamer. All these have to be precisely controlled in time and location, usually utilizing the Global Positioning System (GPS). In the case to use a large ship, an antenna position of the GPS system must be considered. Handling high air pressure equipment requires extra safety considerations.

### ***Ship capability***

Once one knows the OBSs can be put onboard, the other things to consider are the electrical, mechanical, and Internet Technology (IT) specifications on the ship one plans to utilize to service the instruments. Electrical voltage and frequency (and its accuracy) are some elementary factors to know. If the ship is used for both launching and recovering from the sea a free-fall pop-up package, one will need to discuss with the ship operator how to conduct these operations. One may need more than one method depending on the sea and wind conditions and so widen the margin for successful operations. The release into the water and the capture from the water are the times when things may go wrong such as unwanted impact of the instrument into the ship's hull.

GPS is available on every research vessel, but you will want to know how to obtain the data in digital format including timing information. Keeping accurate time on a ship has been a challenge for many centuries, but is now solved to microsecond accuracy by satellite (GPS) technology. The ship must also be equipped with an accurate depth measurement system. Recent swath bathymetry data are desirable for choosing the drop point of the OBS and so avoiding locally steep slopes that may not let the seismic sensor in the OBS be leveled. Existing bathymetric maps of an area can be used to pick locations for OBSs if the map was made with GPS navigation. GPS based bathymetric maps have an accuracy of better than 100 m, whereas maps based on older data may be too poorly navigated to be useful for choosing OBS locations. Even with a map, checking with a deep echo sounder to be certain of the depth before the OBS is deployed should be attempted.

Communication to OBSs is done by sending and receiving acoustic signals from the ship. Sometimes it becomes difficult to maintain this communication link because of ambient noise, particularly from the ship's engine. Testing and understanding the communication link in various situations is an important practical knowledge to have for successful recovery of OBSs.

### ***Applying for and sharing ship time***

Applying for and sharing ship time is different in each country. There is an international database of ocean research vessels where one may find websites of interest (<http://www.pogo-oceancruises.org>). After getting a successful proposal through peer review and the proposal is accepted, one may find one is required to share a cruise with other research groups or that one has been allotted less than the desired number of cruise days. In such cases, one must prioritize to achieve one's goals within the plan. Usually there will be a chief scientist assigned for such coordination well before the cruise. Unlike on land, there may be scientists from different disciplines such as physical and chemical oceanography or marine biology on a cruise. Even within the solid Earth sciences, there could be geomagneticists, geologists, etc. One may need to explain and demonstrate the importance of your science.

### ***Legal matters***

It is necessary to know under which jurisdiction lies the area of your interest (see [http://www.un.org/Depts/los/convention\\_agreements/texts/unclos/UNCLOS-TOC.htm](http://www.un.org/Depts/los/convention_agreements/texts/unclos/UNCLOS-TOC.htm)).

Generally working in the open sea poses no problem for scientific research except that one needs to comply with international rules protecting the environment. If it is within your territorial waters or within your EEZ (Exclusive Economic Zone), you must notify your own country's authorities. If it is within foreign countries' EEZs, permission must be sought through proper channels (which may be your funding agency). It is important to remember that it may require 8 months or more for permission to be either granted or denied. If EEZs are not well defined due to territorial disputes, you may not be able to conduct any

experiments. Clarifications will require consultation with your Foreign Ministry. There could be different conditions to be met in order to conduct seismic observations in these waters on a case-by-case basis. Difficulties may be encountered in conducting active source experiments due to environmental reasons. Relevant information should be available from the managing body of the research vessel. If the vessel enters foreign waters, then one must follow export/import rules for that country, and also the security export rules for your country of origin.

### ***Environment***

Keeping marine ecosystems healthy is recognized as being more and more important. One should not pollute the ocean nor significantly influence the ecosystem. OBS observations should not pose much of a problem in this respect. When conducting an experiment, one may be required to negotiate with fishermen through respective authorities. Unlike commercial companies who may pay compensation to the fishermen for obstructing their work, scientific researchers have traditionally negotiated agreements allowing them to conduct experiments subject to certain time and space limitations but without paying compensation. This means one must know the fishing seasons for different groups of fishermen working in the area of interest. There could also be military operations in the area of one's interest, and one should consult with pertinent authorities such as the Coast Guard. Shipping lanes can be noisy for seismic observations. The best weather window should be sought to avoid stormy, windy, or foggy seasons.

#### **7.5.1.3 Sea water and unconsolidated sedimentary layer**

Any OBS on the seafloor has a sea water layer above it so that corrections for topography are required when analyzing data. The water layer at the seafloor cannot be considered a free surface and needs to be appropriately treated unless one is only interested in traveltimes (e.g. Shinohara *et al*, 1994; Thorwart and Dahm, 2005). For controlled source experiments, where shots occur at the sea surface, how the seismic ray travels in the water column can be important. The sound velocity in the water column has a depth profile that changes geographical area and season and is mainly controlled by lateral and vertical variations of water temperature and salt content. For example, water temperatures may be very different in the same latitudes, e.g. due to the warm Golf stream in the Atlantic or the cold streams on the west coast of North America, or when going along an E-W profile from the Mediterranean Sea with 4.5% salt content to the Azores with about 3.5%. Including these considerations in modeling ray paths rather than assuming a constant velocity layer in the water column leads to more accurate structural models.

An unconsolidated sedimentary layer is almost ubiquitous at the ocean bottom. This layer, which can be from a few hundred meters to a few km (or more in some cases) in thickness, must be treated appropriately in data analysis. The P velocity is only slightly faster than the velocity in the seawater in this layer because the pore water dominates the sediments, but the layer is capable of shear wave transmission. There can be a rapid velocity increase with depth as the pores are squashed. OBS data cannot distinguish this layer very well since all refracted phases travel nearly vertically in this layer to the OBS. Resolving how the shallow sedimentary layer varies in space may require that reflection seismic data be acquired over the OBSs. Usually the top of the igneous crust does not run parallel to the seafloor bathymetry as sedimentation occurs after formation of the crust.

### 7.5.1.4 Noise

The quality of data from the seafloor stations is lower than that of data from most land stations because of the seafloor's much higher noise environment. The ocean surface generates microseisms (Longuet-Higgins, 1950) that at some frequencies may be much stronger than magnitude 6 earthquake arrivals at teleseismic distances (Webb, 1998). Understanding the nature of seismic noise at sea floor is important to understanding seismic observations on and below the sea floor. Unfortunately, noise is also generated by the interaction of seawater flow with the seafloor or with the seismometer at the sea floor. The flow at the bottom of the ocean can degrade long-period performance at 10 sec and longer by directly tilting the seismometer or by deforming the surrounding media (Webb, 1988). The noise amplitudes from tilting can be larger than the amplitudes of most long-period teleseismic phases especially on horizontal-component records. For examples, characteristics of long-period noise in the Atlantic and Tyrrhenian Sea have been obtained using hydrophone, pressure gauge and seismometers (PMD) (Dahm *et al.*, 2006). Seismometers in boreholes into the sea floor, present the best environment to study the nature of seismic ambient noise at the sea floor by avoiding flow noise (Fig. 7.71). Crawford *et al.* (2006) showed a results that the seismic noise in an unsealed borehole is larger than that on the sea floor by removing tilt noise due to fluid flow from the data from the 1998 Ocean Seismic Network Pilot Experiment off Hawaii. Their result indicates that cementing of seismic sensors in a seafloor borehole is essential to reduce a seismic noise in a seafloor borehole.

**Fig. 7.71** Difference of typical noise power spectra in a borehole installation and a seafloor installation near the borehole of site JT1 (see Fig. 7.80). The seafloor observation is noisier than that in the borehole and the horizontal components are much noisier than the respective vertical (Z) components (after Araki *et al.*, 2004).

In 2000 and 2001, state of the art borehole broadband seismometers were installed in the northwestern Pacific Basin (WP-2) and the Philippine basin (WP-1) (Shinohara *et al.*, 2006). The depths of sensors are 561m and 460 m below the seafloor. The seismic data from the WP-1 and WP-2 seismological observatories enable the study of broadband seismic noise in the frequency range from 3 mHz to 50 Hz in the northwestern Pacific over an observation term covering more than one year of continuous recording. Temporal changes in ambient seismic noise within deep-sea borehole can be analyzed in depth using this data (Fig. 7.72). The noise level as a function of time and period for vertical and horizontal components of the WP-1 and the WP-2 observatories were obtained. The major advantage of borehole observatories is that there are little or no temporal change in noise levels for periods longer than 10s. It is found that the noise levels in the vertical component at the WP-1 reach -180 db (rel  $(\text{m/s}^2)^2/\text{Hz}$ ) for

time-periods between 10 s and 100 s, much lower than noise levels for instruments on the seafloor. In contrast, small temporal variations (maximum fluctuations of 10 dB) in noise levels for periods about a few seconds are seen, which can be correlated with the seasonal variability of ocean microseisms (see Chapter 4).

The WP-1 observatory recorded relatively large noise levels in summer and fall at periods of 4 - 8 s. The vertical component of the WP-2 observatory has minimum noise levels about -145 db, which is relatively high noise level. The high noise level of the vertical component of the WP-2 may be due to damage during installation of the sensor. The noise levels in the horizontal components of WP-2 seismometers are -160 db for periods between 10 s and 100 s and thus lower than that of the vertical component. The records from the WP-2 observatory reveal high noise levels in a period range of a few seconds during winter, which is thought to be the mean stormy season which also generates the largest ocean microseisms observed on land-based seismic stations. For both the vertical and the horizontal components of both the observatories, the noise levels are close to the New Low Noise Model (Peterson, 1993) near 10 s period. In general, the peak in the noise spectrum near a period of 100 s in measurements taken at the seafloor or in a shallow-sea borehole is due to deformation of the seafloor by ocean gravity waves (Webb, 1998). Araki *et al.*, (2004) reported that installation of a seismometer in the basement rocks minimize the effects of the ocean gravity waves. Because all the seismometers of the WP-1 and WP-2 observatories were installed into basaltic basement, there is no peak due to the ocean gravity waves.

The horizontal component records of the WP-1 observatory have larger noise levels than the vertical component records for periods longer than 20 seconds. There is a possibility that the horizontal sensors in the WP-1 seismometer have a coupling problem. In contrast, the noise level of the vertical component for periods longer than 10 seconds in the WP-2 observatory is larger than those of the horizontal component. The vertical sensor of the WP-2 observatory may be damaged. In Fig. 7.72 we have plotted representative noise power spectra measured at the WP-1 and WP-2 borehole sites, together with respective spectra from 3 other borehole sites in the Western Pacific (JT1; for positions, also of WP-1 and WP-2 see Fig. 7.80), the North Atlantic (OFP), and the Central Pacific off-coast Hawaii (OSN1). The spectra of the WP-1 and WP-2 is estimated from one hour record for quite season of each site. Note that all borehole installations have almost the same noise level.

**Fig. 7.72** Comparison of ambient seismic noises from seafloor borehole installations: a) for vertical component; b) for horizontal component. WP-1, WP-2 and JT-1 denote borehole

observatories in the western Pacific. OFP and OSN-1 indicate borehole observatories in the North Atlantic Ocean (Montagner *et al.*, 1994) and the Pacific Ocean off Hawaii (Stephen *et al.*, 1999), respectively. NHNM and NLNM indicate the New High Noise Model and the New Low Noise Model by Peterson (1993), respectively.

#### **7.5.1.5 Sensors**

Seismic sensors for land stations are selected according to types of observations needed. The possible choices of sensors is not very wide for OBS observations because the requirement for low power consumption and the limited volume available for the sensors within most pressure capsules. For more general information on the theory, principle design and calibration of seismic sensors and their technical specifications the contributions by E. Wieland (Chapter 5 and DS 5.1).

##### ***Geophones***

The 4.5-Hz exploration-type geophone is mainly used for local and regional earthquake observations. This geophone is also useful for seismic exploration using airguns and explosives. The geophone has the advantage of no power-consumption and small size. The geophone measures signals from approximately 1 to 100 Hz, with a corner frequency at 4.5 Hz. They have a flat response to ground velocity for frequencies greater than this corner frequency. A typical example is the Mark Products L-28. The 2Hz geophone such as the Mark Products L-22 is also used, however, the volume of this sensor unit is larger.

##### ***Active type (moving coil)***

There are also active seismic sensors (Lennarts) on the market which extend the flat velocity output frequency range of 4.5-Hz geophones electronically (see DS 5.1). This sensor has the advantage of small size for its corner frequency of 1Hz. Because land observations for local earthquakes often use 1-Hz sensors, this sensor is useful for combined analysis of land and OBS data.

##### ***Active type (liquid)***

The seismometer (PMD) (see DS 5.1) is a three-component seismometer having a fairly broad frequency band response. The velocity amplitude response is essentially flat from 25 to 0.03 Hz with useful output down to 0.01 Hz. The PMD seismometer sensors are robust and require no leveling or clamping. This makes them particularly suitable for sea floor observation. The inertial component is a liquid—water with potassium iodide in solution—in a container which includes permeable grids that serve as cathode and anode. Between the grids a small bias voltage ( $<0.7$  V) is applied, resulting in an ion current. Vibration of the instrument produces changes in the motion of the ionized liquid through the electrodes, resulting in a modulation of the ion current. These modulations are the output signal of the seismometer. From observation, the power spectral density instrument noise level is about -150 dB [ $(\text{m/s}^2)^2/\text{Hz}$ ] at frequencies between 30 and 10 mHz. This is  $\sim 13$  dB higher than for a CMG-1T broadband seismometer. Below 30 mHz, the performance deteriorates (Shiobara and Kanazawa, 2009).

##### ***Servo-type accelerometer and MEMS***

The up-to-date servo accelerometer or MEMS is also suitable as a seismic sensor for sea floor observation, because they have high resolution and stability. The primary advantage for this type of accelerometer is its compactness, however the power consumption is large and the noise floor of these sensors is slightly higher than the New High Noise Level (Peterson, 1993;

see also Chapter 4). However, because the accelerometers can measure accelerations larger than 1 g, these are useful for studying the source processes of large nearby earthquakes.

### ***Broadband sensors (CMG-1T, CMG-3T)***

Broadband (BB) sensors have a flat response to ground velocity from approximately 0.01 to 50 Hz. Typical examples are the Guralp CMG-1T or CMG-3T seismometer (for specifications see DS 5.1) with frequency range from 0.03 to 50 Hz. The BB sensor provides more information compared to conventional short period (SP) seismometers. However, BB seismometers are more expensive, more fragile and more difficult to deploy, operate, and maintain. Data retrieval and analysis can be more complicated than for geophone sensors. BB seismometers use active feedback to the sensor mass and so require a stable, large power supply. In addition, the seismometers may require control of mass centering so that the recorder must continuously monitor the status of the sensor and autonomously control the sensor. Since BB sensors record microseisms over a much wider period range their raw output signal contains much more seismic noise than signals from a short-period geophones. This means that the recorder needs to have a larger dynamic range for A/D conversion.

The vertical sensor in the Guralp sensors is a modified Lacoste type, and the horizontal sensor is an inverted pendulum. The inertial mass is a boom (a solid machined beam) supporting a transducer coil. The vertical sensor mass is supported by a prestressed triangular spring to support its weight and has a natural period of  $\sim 0.5$  s. The horizontal sensor mass is centered by an unstressed flat triangular spring and has a natural period of  $\sim 1$  s. The effective mass of each sensor is  $\sim 180$  g. The springs are connected to the frames with a temperature compensating wire that minimizes the effect of temperature variation. A compact design is achieved chiefly by the short stiff springs and short boom. The adjustments required for operation consist of leveling the boom of the vertical sensor and tilting the bases of the horizontal sensors to center the mass movements in their equilibrium positions. These are made by small (1 cm in diameter and 3 cm long) direct current (DC) motors operating gear mechanisms to tilt the horizontal sensor bases and to apply a small extra force to the vertical sensor's boom. Before and during the installation, the instrument may be subjected to severe motion that can damage the mass support hinges. Therefore, the masses must be locked securely in their frames so that the hinges can be released after installation. This operation is performed by a small motor-driven clamp, which is controlled by a recorder.

The sensors employ feedback to expand their bandwidth and dynamic range. The sensor's response is determined by the characteristics of the feedback loop. The mass position is sensed by the capacitive position sensor. The voltage from the sensor, which is proportional to the displacement of the mass from its equilibrium position, is amplified and fed to a coil on the mass. The current in the coil forces the mass to its equilibrium position. With a high loop gain, motion of the mass is essentially prevented; the feedback voltage is then a measure of the force and, thus, the acceleration applied to the mass. The block diagram of the feedback system is shown in Fig. 7.73. The system velocity response is identical to that of a conventional long-period sensor with a velocity transducer whose natural resonant period is 360 s with a damping factor of 0.707. The velocity output (flat to 100 Hz) is low-pass filtered ( $< 50$  Hz) before digitization. The mass position output can be used for periods longer than 360 s.

**Fig. 7.73** Example of block diagram of broadband sensors. Frequency ranges depend on product model (Guralp model).

### ***Levelling of sensors***

It is more difficult to level seismic sensors on the sea floor because humans can not access the sensor in the OBSs directly. Although some sensors do not require leveling, most seismic sensors do. There are two types of leveling systems; passive and active leveling. The passive leveling system uses a gimbal mechanism that levels under the force of gravity and strong damping from placing part of the gimbal mechanism in a high viscosity liquid such as silicone grease. Although this system has a simple mechanism, it is difficult to level sensors with natural periods of more than one second with sufficient accuracy. For broadband sensors, an active leveling system is used. The active system also has a gimbal mechanism, however, the gimbal mechanism is driven by micro-motors and fixed by brakes. The leveling system has two tiltmeters and sometimes also a compass. The Central Processing Unit (CPU) reads the tilt of the sensors and controls the motors to level the sensors. The system levels the sensors before starting the observation and after deployment on the sea floor,. In addition, the system checks the level daily. Both passive and active leveling systems typically work over angles of up to 20 degrees.

### **7.5.1.6 Data recording**

#### ***The necessity of low-power compact systems***

All autonomous OBS systems require a low-power recording unit, because the power-supply will be limited. For example, the power consumption of a recorder developed by Earthquake Research Institute (ERI), the University of Tokyo, is less than 0.3 Watts. The system must be compact due to the limited capacity of most pressure vessels. All system units including the sensors, recording system and battery pack must be accommodated within a sphere type pressure vessel of about 50cm diameter.

### ***A/D conversion***

Modern data acquisition systems are based on continuous integration and oversampling in combination with carefully designed digital low-pass filters. In most modern seismic recording systems, a Delta-Sigma-Modulator is used for analog to digital conversion (ADC). The Delta-Sigma ADC needs much electric power, so that it is difficult to use in the conventional way for OBS systems. For some systems the ADC is turned on intermittently to reduce the electric power consumed by the OBS recording system. Some systems still use ordinary successive approximation register A/D converters and sample-and-hold techniques to reduce power-consumption.

#### ***Data storage media (Tape, MO, HD, Memory)***

In OBS observations with continuously recording instruments, an OBS collects about 30-50 M Bytes of data per day for a 3-component station with 100 Hz sampling rate. Early OBS recorders were based on the Analog Direct Recording method in order to record this huge amount of data. Later quarter inch tape and other cassette tapes and in the early 1990s, Digital Audio Tape (DAT) was often used (Shinohara *et al.*, 1993). At present hard disks (HD) are common as mass storage technologies in OBS systems. HDs are reliable, low-cost and robust and allow for much faster data access than other media for mass data storage like tapes. However, the power consumption is significant when the disk is spinning up. An advantage of hard disks as opposed to other magnetic- and opto-magnetic media is that they are encapsulated and less sensitive to rough and dusty environments. For connecting the hard disk to the recorder, many systems use the Small Computer System Interface (SCSI) others use the Integrated Drive Electronics (IDE) interface. With respect to data transfer, SCSI systems are more reliable than IDE systems, however the latter are less costly. Memory systems such as Compact Flash card (CF) and Secure Digital memory card (SD) now have sufficient capacity for data storage and are rapidly replacing other media in OBSs. For example, the capacity of SD now exceeds 32 GB, which is enough for continuous recording for a few months. These memory systems have no moving parts, and are quite robust.

## **7.5.2 Ocean Bottom Seismograph (OBS)**

### **7.5.2.1 Introduction**

There are two types of equipment for seismic observations in marine environments: pop-up type OBSs and cabled OBSs. The pop-up type OBS is a stand-alone system. These are deployed on the sea floor by free-fall from a research vessel, and are recovered by pop-up after releasing an anchor. The advantages of the pop-up OBS are low-cost for the equipment and observations and that they can be deployed anywhere. However, the data are obtained only after recovery of the OBSs (Fig. 7.74). At the present, pop-up OBSs can be classified by type of sensor, and observation term. Cabled OBS can send data in real-time and power is supplied from land. This means there are fewer limits for power consumption by the OBS. Real time data is required for earthquake monitoring in the context of alarm and disaster mitigation schemes. The disadvantage of cabled OBSs are the high cost. As examples both types of OBSs, as developed and used in Japan, are described in the following in more detail. For technical specifications see section 7.5.4.

**Fig. 7.74** Schema of seafloor observation using pop-up type OBS.

### 7.5.2.2 Pop-up type OBS

#### *Short-term OBS*

In recent years, ocean bottom seismometers (OBSs) have been used to obtain crustal and upper mantle seismic structure and the distribution of earthquakes. Before the 1990's, the OBSs used in these experiments worked with analog recording tape. One of the advantages of analog recording OBSs was that they could record data continuously for more than two weeks. A disadvantage of the analog OBSs was their limited dynamic range per recording channel.

A digital recording short-term OBS (ST-OBS), which has the same recording length of time as the analog OBSs, was developed to obtain higher quality data. The ST-OBS consists of one pressure vessel, an acoustic release system, a radio transmitter, and a strobe light (Fig. 7.75). The pressure vessel (glass sphere) contains sensors, recorder and battery cells. The design of ST-OBS, except for the digital recorder, is the same as the analog recording OBS. First, a commercial portable digital audio tape (DAT) recorder was used to store seismic data to obtain long-term recording at low power and low cost. Next, 2.5 inch SCSI hard disk was used to store data. The use of hard disks has allowed a longer recording period. The latest recorder has memory media such as Compact Flash memory (CF) or SD memory. The first practical digital recorders had 16-bit A/D converters and thus a dynamic range of 96 dB. Nowadays, 24-bit A/D converters are common which allow a dynamic range of up to 144 dB. Recorders usually record 3 or 4 channels of data continuously at 100 or 128 Hz sampling rate. A real-time clock (RTC) with an accuracy of order  $10^{-8}$  controls timing of the recording system including the timing of A/D conversion, the starting of data acquisition at a predetermined time, and so on. The electric setup and monitoring of the recorder inside the sealed vessel, including adjustment of this RTC, can be performed by connecting a computer to the recorder through the pressure vessel. A timing clock pulse is output to outside of a pressure vessel allowing comparison of the RTC of the recorder to a time standard provided by a GPS receiver. The data on the recording media is retrieved after recovery an OBS.

**Fig. 7.75** Top view (upper) and side view (lower) of ST-OBS layout. The glass sphere housing instruments has a positive buoyancy and is released by acoustic command. External mechanical configuration has not changed from that of the analog recording OBS (after Shinohara *et al.*, 1993)

### Long-term OBS

Long-term OBSs (LT-OBS) were developed at ERI to observe earthquakes continuously on the sea floor over more than one-year. For the housing of the LT-OBS, a titanium-alloy sphere made in Russia with 50 cm diameter was selected, so as to avoid problems from corrosion of the pressure vessel (Fig. 7.76). The titanium-alloy vessel was tested for use at 6,000m depth before shipment from the maker. Lennartz's LE-3Dlite is used for the short-period sensors in this OBS operating with a velocity-proportional response in the frequency range between 1 and 80 Hz. Three component sensors are mounted on a leveling system. The leveling unit is equipped with two tiltmeters which have 0.1 degree accuracy. The outputs of the three seismometer components are amplified by a low-noise and low-power analog unit, and are converted to 22-bit digital signals continuously. The sampling frequency is either 200Hz or 128Hz. Data are stored in memory temporarily. When the memory is full, the data on the memory is transferred to Hard Disk (HD). Power to all electric circuits (CPU, sensors, leveling system, and HD) are supplied by lithium battery cells. Each cell has a power capacity of 30Ah. Although the number of battery cells depends on the intended duration of recording, approximately 50 battery cells are needed for one-year of observations. The LT-OBS is equipped with an acoustic release and communication system. The most important function of the acoustic system is to release a weight for recovery. After an acoustic release command is sent from a shipboard unit, the acoustic system on the OBS provides electric power to a weight release unit causing rapid electrical corrosion of the strap holding the weight. Another function of the acoustic system is communication between the sea floor and sea surface. The recording unit on the OBS can be controlled from the on-board unit, for example, starting or stopping recording, leveling the sensor, and checking the status of the recording unit. This type of LT-OBS is widely used for monitoring earthquake activity in Japan. At the present, approximately 200 LT-OBSs are in operation in Japan.

**Fig.6** Perspective cutaway of the LT-OBS. The titanium-alloy vessel contains seismic sensor, recorder and batteries. The duration of recording of the LT-OBS reaches one year.

### ***Broadband OBS***

Based on long experience with the short-period OBS, a broadband OBS (BBOBS) has been developed at ERI as well. This OBS is equipped with broadband sensors. This system is also mobile, compact, reliable and easy to operate and enables long-term observations. These BBOBSs have been used since 1999, yielding good scientific results and offering more opportunities for observations, especially in the long-period range. The design of the BBOBS (Fig. 7.77) is quite simple, as all units are inside of a housing made of titanium. These BBOBS also use self pop-up for recovery. The key design points were low power consumption of the sensor and recorder including the precise RTC clock, and low weight for the OBS so as to maintain positive buoyancy despite the limited volume of the housing. The titanium-alloy pressure vessel has a diameter of 65 cm, which is slightly larger than the LT-OBS, as required to contain the BB seismic sensor with its larger volume and additional batteries needed to power the BB sensor. The sensor was specially made for our active leveling unit and it is possible to physically separate the mechanical part and the main electronic boards. When the BBOBS is deployed at the deep sea floor, the inside of the housing is an ideal operating environment for the sensor (and also the crystal-oscillator clock) because of small temperature variations experienced and absence of human activity compared to land observatories. The amount of the data stored is about 4 GB for one month if the sampling rate is 200 Hz for three components and when using a completely recoverable compression method. The quality of the data is described in a later section.

**Fig. 7.77** Photograph of the BBOBS before deployment. The shape of the BBOBS is similar to that of the LT-OBS, however, the pressure vessel is larger than that of the LT-OBS due to sensor size.

### ***Ocean bottom accelerometer (OBA)***

To understand the characteristics of large earthquakes which occur in a subduction zone, it is necessary to study the asperities, where large earthquakes may occur repeatedly, from a close distance. Since a conventional OBS is designed for high-sensitivity observations, OBS records of large earthquakes which occur nearby are often saturated. A servo-type accelerometer is well-suited for recording large amplitude seismic waves. However it was difficult to use such an accelerometer in OBSs due to the large electric power consumption. Recently, a servo-type accelerometer with a large dynamic range and low-power consumption has been under development. Alternatively, one can use a larger size titanium sphere pressure vessel for the OBS and so contain many more batteries. For long-term sea floor observations of large earthquakes, a small three component accelerometer is installed into conventional long-term OBSs for acquisition of low-sensitivity (strong motion) accelerograms of the sea floor. For example, we use a compact three-component servo-type accelerometer with a weight of 53 grams as the seismic sensor. Measurement range and resolution of the sensor are 3 g and  $10^{-5}$  g. The sensor is directly attached to the inside of the pressure vessel (Fig. 7.78). Signals from the accelerometer are digitally recorded to Compact Flash memory with 16 bit resolution and a sampling frequency of 100 Hz. The OBAs have been deployed several times and accelerograms obtained on the sea floor. One earthquake with magnitude of 7 was recorded by the OBA at an epicentral distance of approximately 20 km. The maximum acceleration reached  $5.5 \text{ m/s}^2$ . Continuous improvements are being made to the system to obtain better quality data.

**Fig. 7.78** Installation of the accelerometer to the inside of the pressure vessel (Type 1). The accelerometer was fixed beside the conventional three-component seismometer with gimbal mechanism with the same orientation (after Shinohara *et al.*, 2009).

### **7.5.2.3 Cabled OBS system**

In this section some of the existing and planned OBS cabled systems are described. In Japan, a number of optical-cable linked ocean bottom seismic stations and tsunami stations have been deployed since the 1990's (Fig. 7.79). Cabled geophysical observation systems are deployed off Hokkaido, Sanriku, Boso, Izu, and Shikoku. In 1994, the Earthquake Research Institute, University of Tokyo deployed a cabled OBS network system around an earthquake swarm area off Izu. Data from three seismic sensors on sea floor are transmitted on-line by using optical fibers to a land station. In 1996, an ocean bottom geophysical observatory using a sea floor optical fiber cable was installed off Sanriku. The Sanriku system has three seismometers and two tsunami gauges. These data are transmitted to a land station in real-time by individual fibers. The sea floor optical fibers are buried in areas where the water

depth is less than 1,000 meters to protect the cable from fishery activities. These systems provide integrated observation from both on land and under the sea. The disadvantages of the existing cabled OBS systems are their high cost and limited adaptability. Once the system is deployed, it is very difficult to add sensors for new observation. The Japan Agency for Marine-Earth Science and Technology (JAMSTEC) is constructing a new cabled OBS system using wet-mate-able connectors. Sensors can then be replaced using a Remotely Operated Vehicle. The system will be deployed off central Japan where a huge earthquake is expected to occur. These existing systems are based on the technology of trans-ocean communication cables which need high reliability. However, since the existing system is so expensive, it is difficult to deploy many observation nodes for experimental use, for example when it is important to observe earthquakes using a spatially high density seismic network. Therefore a new cabled OBS system is being developed using Internet-Technology to lower the cost for spatially high density seismic observations (Kanazawa and Shinohara, 2009). This system is planned to be deployed in the Japan Sea during 2010.

**Fig. 7.79** Locations of cable OBS system for local earthquake observation around Japan. Numerals indicate the number of observation nodes for each system. Operating agents are also shown. Note that the existing cable OBS systems have a small number of observation nodes. TM-1 and TM-2 indicate positions of real-time tsunami-meter.

#### 7.5.2.4 Ocean floor borehole system

The Japanese Ocean Hemisphere Network Project installed four borehole geophysical stations at three sites covering a period from 1999 to 2001 (Fig. 7.80). In 1999, two borehole stations (JT-1 and JT-2) were installed during Ocean Drilling Program (ODP) Leg 186 (Sacks *et al.*, 2000) and are located immediately above the inter-plate earthquake generation zone on the landward side of the Japan Trench. The JT-1 and JT-2 stations were installed approximately 50 km apart and have two broadband seismometers, a strainmeter and a tiltmeter for each station. In August 2000, during ODP Leg 191, the borehole seismological observatory WP-2 was successfully installed at ODP Site 1179 in the northwestern Pacific basin (Kanazawa *et al.*, 2001). Borehole seismic observatory WP-1 was installed in the west Philippine basin during ODP Leg 195 in April 2001 (Salisbury *et al.*, 2002). The WP-1 and WP-2

observatories each have two identical broadband seismometers (Guralp CMG-1TD). Together, these observatories can cover a large expanse of the northwestern Pacific in areas that comprise major gaps in the coverage provided by pre-existing global seismological observatories. At present, the data from these four borehole observatories are retrieved by ROV visits at an interval of about 0.5 - 1.5 year (Suyehiro and Mochizuki, 2002). Araki *et al.* (2004) have already reported on the JT-1 and JT-2 observatories and the characteristics of the geophysical data obtained from the JT-1 observatory.

**Fig. 7.80** Location map of broadband seismic station coverage in the north-west Pacific. Small blue and yellow circles indicate land seismic stations, orange circles are seafloor borehole observatories, which were installed by drilling vessel. The JT-1 and JT-2 were deployed in 1999. The WP-1 and WP-2 observatories were installed in August 2000 and April 2001, respectively. These sea floor observatories successfully captured broadband seismic data for a few years.

#### 7.5.2.5 Dealing with a multiple-OBS long-term dataset

As LT-OBS and BBOBS data became more available, a huge amount of the data is being obtained from these OBSs. One ST-OBS generates less than 100 Mbytes of data during a few months of observations. For one year of observation using LT-OBSs, the amount of the data becomes approximately 20 GB for each LT-OBS. A single array deployment for earthquake observations can use more than 20 LT-OBSs, so that the total amount of the data from the OBS network will be about 0.5 T bytes. The data collected by the OBSs are stored on 2.5 inch HD in a format which depends on the recorder. After the recovery, the data on each 2.5 inch HD must be copied to an ordinary computer using a data reproduction system. The data reproduction system requires a fast speed for data transfer and a huge capacity disk array. Usually, these features are obtained by using an up-to-date CPU and a disk array with a capacity of more than 1 T bytes with a fast interface (e.g. fiber connection).

For OBS observations, each OBS has its own clock. After the transfer of the data, time adjustments for each OBS record are required. The time difference between each OBS clock and a GPS clock is measured just before deployment and just after recovery. Because the temperature of sea water is constant on the deep sea floor, the crystal oscillator should also be at constant temperature on the seafloor. A linear drift in time to the timing offset of the crystal oscillator is assumed, and used to adjust the time stamp of the record to the correct GPS time. After the time adjustment, each OBS record is combined to construct multi-station files for the whole observation period. During this procedure, multi-station files with a time length of one (or a few) minutes are created for easy handling of the data. Time of multi-station files is continuous so that it is easy to make more longer multi-station file for picking up arrivals.

Because a huge number of files are generated as a result, a powerful computer with a large capacity disk array is also needed for this procedure. After that point, the data processing (e.g. event detection) is the same as for land seismic networks.

#### 7.5.2.6 State of OBS activities

In Japan, the development of OBSs was started at the Geophysical Institute, and ERI of the University of Tokyo in 1970's, and now continues at ERI. These groups developed various types of OBSs for surveys of Earth structure and earthquakes observation (e.g. Mochizuki *et al.*, 2008). A few universities have ST-OBS for seismic surveys and local earthquake observations. At present a few governmental institutes have ST-OBSs and are operating cabled OBSs. JAMSTEC has a few hundred ST-OBSs and a smaller number of LT-OBSs and BBOBSs. Their ST-OBSs are mainly used for seismic surveys (e.g. Kodaira *et al.*, 2004).

The U. S. National Ocean Bottom Seismograph Instrument Pool (OBSIP) has provided instrumentation to support US funded research programs requiring OBSs beginning in 2000. The Lamont-Doherty Earth Observatory at Columbia University, the Scripps Institution of Oceanography at the University of California San Diego and the Woods Hole Oceanographic Institution each have developed and now maintain OBSs for the US OBSIP, including ST-OBSs, LT-OBSs and BBOBSs. The ST-OBSs in the OBSIP can record for about 2 months and use for sensors both geophones and hydrophones. Principal investigators at research universities can request the use of instruments as part of the standard NSF proposal process. Many experiments supported by OBSIPs have been carried out (e.g. Pozgay *et al.*, 2009 for the MARIANA experiment).

The Leibniz Institute of Marine Sciences at Kiel University (IFM-GEOMAR) in Germany has both OBSs and Ocean Bottom Hydrophones (OBHs). OBHs were first developed and then OBSs were developed based on the experiences with the OBH. In 2002 a completely revised design was developed for the OBS system to enable the operation of either short period or broadband seismometers. The recording term of BBOBS is up to one year. In Germany, the Institute for Geophysics at Hamburg University and Alfred Wegener Institute in Bremerhaven have also developed and operate OBSs. These institutes are actively carrying out experiments (e.g. Dahm *et al.*, 2002). The German Instrument Pool for amphibian seismology (DEPAS), which is operated by the Alfred Wegener Institute für Polar und Meeresforschung, Bremerhaven, uses Guralp CMG 40T (60 sec) sensors in titanium pressure cylinders ([http://www.awi.de/en/research/research\\_divisions/geosciences/geophysics](http://www.awi.de/en/research/research_divisions/geosciences/geophysics)). At present, the DEPAS has a large scale facility of broadband OBS (80 instruments) (Friederich and Meier, 2008). Hamburg University and GEOMAR use SEND Geolon MLS data logger with a power consumption of 0.25 W, 21bit resolution at 50 Hz, and time accuracy of 0.5 ms/day.

The French Research Institute for Exploitation of the Sea (Ifremer) has approximately 20 ST-OBSs for wide angle seismic surveys. The OBS at Ifremer consists of identical recorders based on the GEOMAR data logger and also on their own mechanical design. The Ocean Bottom Instrumentation Consortium (OBIC) in UK comprises three well established academic institutions: the Universities of Durham and Southampton and Imperial College, London. The OBIC has about fifty LT-OBSs, which are mainly used for seismic structure surveys. In 2008, 50 OBSs recorded airgun signals in the source region of the 2004 Sumatra earthquakes, and 10 OBSs were re-deployed to record earthquakes for approximately one year (Barton *et al.*, 2008).

## 7.5.3 Examples of seafloor seismic observations

### 7.5.3.1 Local earthquakes

One of the best examples of sea floor observations is that of the aftershocks of large earthquakes occurring in marine areas. On 25 September 2003 the great Mw8.3 Tokachi-oki earthquake occurred off Hokkaido, Japan. Four days after the mainshock, a deployment of twenty-nine OBS in the source region was started to study the aftershock activity of this event using a chartered ship with a size of 700 tons. From October 19-21, nine OBSs that had been deployed near the epicenter of the mainshock were recovered by a research vessel and the data used to obtain the distribution of aftershocks. Ten OBSs were redeployed at the same sites as the previous deployment to continue the aftershock observations. On October 18 and 19, eight OBSs were additionally deployed to enlarge the observation area. Consequently, the aftershocks were observed at forty-one sites including three cable OBS sites, and forty-seven pop-up type OBSs were used in total. All the OBSs at the sea floor were recovered by a chartered ship with a size of 700 tons from November 17 to 20. The observation area was 150 km x 100 km that covered the high aftershock activity, as estimated from the land seismic network. The station spacing of the OBSs was approximately 15 km in the trench region. In the landward area, OBS were deployed with a spacing of about 20 km because the aftershocks were estimated to occur in this region at depths deeper than 20 km (Fig. 7.81).

Two types of the digital recording OBS system were used. The 46 OBSs had both vertical and horizontal velocity sensitive electro-magnetic geophones with a natural frequency of 4.5 Hz and one BBOBS (Guralp CMG-3T). Accurate timing, estimated to be within 0.05 s, was provided by a crystal oscillator. All the OBS were a pop-up type with an acoustic release system. The OBS positions at the sea floor were estimated with an accuracy of several meters using acoustic ranging and ship GPS positions. The water depths at the OBSs were determined by the acoustic ranging and hypocenters were determined by using a three-dimensional velocity structure based on a seismic refraction study. According to the obtained epicentral distribution, the aftershocks occurred within the small slip region of the main shock. In addition, the epicentral distribution of aftershocks, except near the large slip region, was similar to that of the earthquakes occurring before the main shock. Although most land-based hypocenters, which included the data from the cabled OBSs, had depths of greater than 20 km, all hypocenters determined by the OBS network had focal depths around 20 km. P and S wave arrivals at seismic stations above a hypocenters are essential in order to obtain precise hypocenter positions. The OBS network satisfies this condition. All hypocenters located by the OBS network were shallower than those determined by the land network (Fig. 7.82) with most of the aftershocks occurring around 20 km depth. The aftershocks form a dipping plane toward the land. It is inferred that this plane shows the upper boundary of the subducting Pacific Plate. The position of the plate boundary estimated by the aftershock distribution is consistent with estimates by the past seismic surveys (Yamada *et al.*, 2005).

**Fig. 7.81** Bathymetric map off-shore of SE Hokkaido with the positions of OBS used for the aftershock observation of the 2003 Mw8.3 Tokachi-oki earthquake. Inverted triangles indicate the positions of pop-up type OBSs, squares the positions of the cabled OBSs, numerals the site numbers, large and small stars the epicenters of the mainshock and the largest aftershock. Gray symbols in the land region show the positions of the permanent seismic stations (after Shinohara *et al.*, 2004).

**Fig. 7.82** Comparison of the distribution of Tokachi-oki earthquake aftershock epicenter (upper left) and hypocenter positions in N-S and E-W projection (upper right and lower left) as determined by the OBS network (gray circles) and by the dense land network on the Japanese islands. Arrows relate the land network locations to the OBS locations (after Yamada *et al.*, 2005)

Simultaneous estimation of the hypocenters and 3-D seismic velocity models from the P- and S-wave arrivals of the aftershocks recorded by OBSs was performed (Fig. 7.83). The subducting plate is clearly imaged as a northwest dipping zone in which  $V_p$  is higher than 7 km/s. The aftershock distribution reveals that the dip angle of the plate boundary increases around 90 km from the Kuril Trench towards Hokkaido from less than 5 degree to 16 degree. The bending of the subducting plate corresponds to the southeastern edge of the rupture area. The island arc crust on the overriding plate has P-wave velocities of 6–7 km/s and a  $V_p/V_s$  of 1.73. A region of  $V_p/V_s$  greater than 1.88 was found north of the epicenter of the main shock. The depth of the high  $V_p/V_s$  region extends about 10 km upward from the plate interface. The plate boundary just below the high  $V_p/V_s$  region has the largest slip at the main rupture. A high  $V_p$  anomaly ( $\sim 7.5$  km/s) is found in the island arc crust in the northeast part of the study area. The rupture of the main shock terminated at this high  $V_p$  region (Machida *et al.*, 2009).

**Fig. 7.83** **Top:** Distribution of 589 relocated aftershocks determined beneath the OBS network. The yellow star and the gray circles represent the epicenters of the 2003 Tokaichi-oki mainshock and its relocated aftershock hypocenters, respectively. Triangles denote positions of the OBSs. Focal mechanisms determined by JMA for the numbered aftershocks are shown at the lower left. Lower hemisphere projection is used. HVZ means the high P-wave velocity zone by the tomography with OBS data. The slip distribution of the main shock after Yamanaka and Kikuchi (2003) is shown by thicker contour lines. The tsunamigenic asperity of 1952 Tokachi-oki earthquake (Hirata *et al.*, 2003) is also indicated (gray regions). **Bottom:** Distribution of the relocated hypocenters projected on the vertical cross section along A-A'. (after Machida *et al.*, 2009)

### 7.5.3.2 Teleseismic events

To investigate the stagnant slab beneath the northern Philippine Sea, we have deployed a large OBS array over the 3 years between 2005 and 2008 (Shiobara *et al.*, 2009). This was a key part of the "Stagnant Slab Project" (SSP) started in 2004 and running for 5 years, because these were the first direct and dense observations above this target area aimed at revealing the fine physical structure of the stagnant slab. The transition of the slab morphology along the Izu – Ogasawara (Bonin) – Mariana arc as shown by a global tomography is also a target of interest to be resolved in high resolution by this experiment. The observation area extended about 1000 km (N-S) X 2000 km (E-W), as shown in Fig. 7.84. The first, second and fourth year's cruises were performed by the R/V Kairei (JAMSTEC), and the third year's cruise was done by a chartered ship. The number of BBOBS deployed was 12, 12, 15 for the first, second and third year observation periods, respectively. All of the BBOBS and OBEMs have been recovered successfully except for one BBOBS that did not come up to the sea surface.

From the noise study of all BBOBS stations, all components showed noise levels at periods around 10 s in the middle between the New Low Noise Model (NLNM) and the New High Noise Model (NHNM) according to (Peterson 1993). The vertical noise data were found to lie

in this same middle level at longer periods, but the horizontal noise levels became then higher than the NHNM (see Fig. 7.85 for site T13). The main reason for this high noise level for the horizontal components is assumed to be caused by variations in the BBOBS's tilt due to the sea bottom currents. But, the lower bound of individual noise spectra used for the noise model reaches the NLNM between 10 s and 30 s in the horizontal component that shows the high noise level in the noise model (Fig. 7.85).

**Fig. 7.84** Location map of BBOBS in the SSP. Orange circles and red triangles show BBOBS sites and land BB seismic stations, respectively.

Results from the dataset from the first and second years of observation include surface wave tomography (Isse *et al.*, 2009) and receiver function analysis (Suetsugu *et al.*, submitted). The former revealed a better resolved upper mantle model for this area than has been seen before. The later study demonstrates clear differences in the mantle transition zone at the edge of the stagnant slab (Fig. 7.86).

### 7.5.3.3 Tsunami events

Three ocean bottom seismographs (OBSs) and two ocean bottom tsunami-meters (OBTMs) were deployed off Sanriku, northeastern Japan by the Earthquake Research Institute of the University of Tokyo. All data from the OBSs and OBTMs are transmitted to land in real-time. On 30 May 1998, a thrust-type earthquake (Mw 6.1) occurred off the Sanriku region. The

two OBTMs, TM-1 and TM-2, which were installed at depths of 990 and 1563 m, respectively, about 80 and 100 km apart from the hypocenter, detected a small tsunami generated by this earthquake. with a peak-to-peak amplitude of only about 1.5 cm and a wavelet period of about 300 s (Fig. 7.87). The OBTMs had quartz-type pressure sensors with pressure resolution and full scale of 0.5 mm and 3,000 m, respectively, and a sampling interval of 100 ms. Hino *et al.* (2001) estimated reliable tsunami source parameters and showed that ocean bottom tsunami-meters are useful for studying plate subduction.

**Fig. 7.87** Tsunami records obtained by the OBTM stations, TM-1 and TM-2. See Fig.9 for positions of TM-1 and TM-2. Ocean tide components were removed and moving average of 60 s length were applied (after Hino *et al.*, 2001).

## 7.5.4 Technical specification examples

### **Specifications of ST-OBS**

Sensor : Tri-axis 4.5Hz~ (-3dB) (Sercel L-28 for ERI)  
Recorder : 24bit, 100/200Hz sampling, 0.29W in average (HDDR5)  
Data media : Firewire HDD (ex. 40GB, max. 4 drives)  
Clock : Within the recorder, MCXO ( $<\pm 0.1$ ppm, QEM77-AH)  
Power : 6 Li cells (for 90 days obs.), DD size (3.9V, 30AH)  
Transponder : Slant ranging, anchor release control  
Anchor releasing : Forced electric corrosion of two thin Ti/Stainless plates  
Housing : Glass sphere ( $\varnothing$  432mm), 25kgw of buoyancy  
Recovery aids : Radio beacon and xenon flasher (Novatech)  
Dimension : 1.0m/1.0m/0.6m (width/depth/height)  
Weight in the air : 80/40 kgw (with/without anchor)

### **Specifications of LT-OBS**

Sensor : Tri-axis 1~80Hz (-3dB), 400V/m/s, 0.1W (Lennartz LE-3D for ERI)  
Gimbal : Active leveling ( $\leq 20^\circ$ )  
Recorder : 24bit, 100/200Hz sampling, 0.29W in average (HDDR5)  
Data media : Firewire HDD (ex. 40GB, max. 4 drives)  
Clock : Within the recorder, MCXO ( $<\pm 0.1$ ppm, QEM77-AH)  
Power : 50 Li cells (for 356 days obs.), DD size (3.9V, 30AH)  
Transponder : Slant ranging, anchor release/recorder control  
Anchor releasing : forced electric corrosion of two thin Ti plates  
Housing : Titanium sphere ( $\varnothing$  500mm), 33kgw of buoyancy  
Recovery aids : radio beacon and xenon flasher (Novatech)  
Dimension : 1.0m/1.0m/0.7m (width/depth/height)  
Weight in the air : 120/80 kgw (with/without anchor)

### **Specifications of BBOBS**

Sensor : Tri-axis 360s~50Hz (-3dB), 1500V/m/s, 0.28W (Guralp CMG-3T for ERI)  
 Gimbal : Active leveling ( $\leq 20^\circ$ ) with fluxgate compass  
 Recorder : 24bit, 100/200Hz sampling, 0.29W in average (HDDR5)  
 Data media : Firewire HDD (ex. 40GB, max. 4 drives)  
 Clock : Within the recorder, MCXO ( $< \pm 0.1$ ppm, QEM77-AH)  
 Power : 78 Li cells (for 400 days obs.), DD size (3.9V, 30AH)  
 Transponder : Slant ranging, anchor release/recorder control  
 Anchor releasing : Forced electric corrosion of two thin Ti plates  
 Housing : Titanium sphere ( $\varnothing$  650mm), 70kgw of buoyancy  
 Recovery aids : Radio beacon and xenon flasher (Novatech)  
 Dimension : 1.0m/1.0m/0.8m (width/depth/height)  
 Weight in the air : 240/160 kgw (with/without anchor)

### ***Specifications of OBA***

Sensor : Tri-axis DC~ (-3dB),  $0.2\text{V/m/s}^2$ , 0.72W (JAE JA-28GA for ERI)  
 Sensor installation : Fixing to pressure vessel  
 Recorder : 24bit, 100/200Hz sampling, 0.29W in average (HDDR5)  
 Data media : Firewire HDD (ex. 40GB, max. 4 drives)  
 Clock : Within the recorder, MCXO ( $< \pm 0.1$ ppm, QEM77-AH)  
 Power : 120 Li cells (for 365 days obs.), DD size (3.9V, 30AH)  
 Transponder : Slant ranging, anchor release/recorder control  
 Anchor releasing : Forced electric corrosion of two thin Ti plates  
 Housing : Titanium sphere ( $\varnothing$  650mm), 70kgw of buoyancy  
 Recovery aids : Radio beacon and xenon flasher (Novatech)  
 Dimension : 1.0m/1.0m/0.8m (width/depth/height)  
 Weight in the air : 240/160 kgw (with/without anchor)

## **Acknowledgments**

The authors of Chapter 7 are thankful to Ahmed Elgamal, C. R. Hutt, Dieter Mayer-Rosa, Jamison Steidl, Rod Stewart and Peter Zweifel, for their reviews and suggestions which have helped to improve the original text. The non-native English-American contributors to this Chapter owe particular thanks to Rod Stewart for his careful English proof-reading of the sub-chapters 7.1 to 7.4. W. Hanka, author of section 7.4.4, also thanks M. Brunner (†) for many excellent ideas and carrying out the shielding experiments and K.-H. Jaeckel for very fruitful discussions around this topic.

The authors of section 7.5 on OBS wish to express thanks to Toshihiko Kanazawa, retired professor of marine seismology, Earthquake Research Institute of the University of Tokyo. Valuable comments from the editor of the NMSOP, Peter Bormann during two careful reviews and many suggestions made on the first and second draft helped to improve the paper. The authors also thank Torsten Dahm, Azusa Nishizawa and Spahr Webb for their critical reviews and recommendations and are particularly grateful to Spahr Webb for the troubles he has taken in polishing up the English draft.

| Topic   | What to prepare and provide if seismic site selection is purchased?                                                          |
|---------|------------------------------------------------------------------------------------------------------------------------------|
| Author  | Amadej Trnkoczy (formerly Kinometrics SA);<br>E-mail: <a href="mailto:amadej.trnkoczy@siol.net">amadej.trnkoczy@siol.net</a> |
| Version | Sept. 1999; DOI: 10.2312/GFZ.NMSOP-2_IS_7.1                                                                                  |

If seismic station site selection procedure is purchased as a part of services along with the seismic network equipment, the purchaser should prepare several logistic things to assure efficient work of the manufacturer's experts. Note that these services are usually paid by the time the experts work on site selection for a new seismic network and that site selection is a 'stretchable' process. The more time (read "money") one spends on it, or the more efficiently one works during a given time period, the better the station sites and, consequently, the network performances will result. Therefore, it is of direct benefit to the customer to consider carefully all the required issues and to get together all the necessary information and working material, as complete as possible under the given conditions in the particular country. The seismic network purchaser should prepare the following:

- a preliminary and approximate proposal of seismic network layout based on the goals of the network;
- a general-purpose "high school type" topographical map of the whole region of the future network with color representation of terrain altitude (basic topographical display of the region);
- regional (and local, if available) geological maps covering the region of the network;
- map of past seismic activity in and around the region where the network is planned, with instrumental (if any) and historic data be included;
- seismo-tectonic map of the region (if available);
- 1:50.000 or 1:25.000 scale topographic maps covering the entire network region for RF profiling purposes for telemetry seismic systems (1:50.000 scale maps are the best; 1:25.000 maps are better for fieldwork if there is no RF telemetry planned in the network). Get permission to export such maps if they are under export restriction, as these will be needed by the site selection provider for initial studies before fieldwork starts, particularly if the network is an RF telemetry system;
- a state-of-the-art roadmap of the country for finding easy access to potential sites during fieldwork. Try to find the latest edition of such map. Road infrastructure changes fast in many developing countries;
- 1:5.000 scale maps (or at least 1:25.000 if 1:5.000 are not available) of the area surrounding the sites in case shallow seismic profiling of potential seismic sites is planned;

- climatic data in the form of maps or tables published in annual or decade reports from the country's meteorological survey (data should include precipitation, wind, insolation - if seismic stations will be powered by solar panels -, and lightning threat information such as isokeraunic maps or number of storm days per year).
- knowledgeable staff members from the institution that will operate the network as well as well informed local people acquainted with local conditions at each potential station site. The member(s) of the responsible institution working in the field, together with manufacturer's experts, should have full competency to make 'on the spot' decisions regarding acceptability of access difficulties, land ownership issues, and other issues that may have financial consequences during network establishment and future network operation. This person should be full time and continuously with the manufacturer's experts until the site selection procedure is finished. If the region of the network is large, several local people may be needed. They can be members of local authorities (municipalities, land-use planning authorities, etc.) and should be familiar with local development conditions and present and future land use;
- one or two four-wheel-drive vehicles in technically perfect condition, one of which should be big enough to comfortably transport four people together with measuring equipment its original packing (two PC notebooks, seismometer, seismic recorder, cables and, in case of telemetry system, RF spectrum analyzer, provisory antenna mast, and Yagi antennae). Two or three customer's staff members (plus driver and enough cash, coupons or whatever documents are required to purchase gasoline) are the best size team to work with usually two manufacturer's experts;
- air-conditioned working room with three tables, main power, and safe storage place for measuring equipment. If the network is an RF telemetry system, one of the tables must be large enough, minimum 1.5 x 3 m (5 x 10 feet), to allow working with several topographical maps stuck together while taking topographical profiles; and
- permits to enter restricted areas (army camps and training land, private land, natural reserves, state border regions, etc.) for local staff and foreign experts.

The maps sent to the site selection provider and used in the field are working copies. They are normally not returned to the customer. The maps are used when preparing the final report. If color maps are code protected against copying, two copies are needed (one for fieldwork and one for the final report).

Expect from one to three days of work for each station site of the network. Any extra time needed will depend on the dimensions of the network, infrastructure in the country, and general site accessibility. An efficient day of fieldwork usually lasts from sunrise to sunset.

**Hint:** Print this form and put check marks in appropriate bullets while preparing on-site selection procedure.

| Topic   | Using existing communication tower sites as seismic sites                                                                    |
|---------|------------------------------------------------------------------------------------------------------------------------------|
| Author  | Amadej Trnkoczy (formerly Kinemetrics SA);<br>E-mail: <a href="mailto:amadej.trnkoczy@siol.net">amadej.trnkoczy@siol.net</a> |
| Version | Sept. 1999; DOI: 10.2312/GFZ.NMSOP-2_IS_7.2                                                                                  |

Very often less experienced newcomers in seismometry consider mountain peaks with existing communication towers as potential seismic station sites, particularly if they are building an radio frequency (RF) telemetry seismic network. Such places appear to be an easy and inexpensive solution. Access problem is solved, RF communication paths to the central recording site, which is usually situated in the capital or another big city, is supposedly free, main power lines, and even phone lines are readily available.

Unfortunately, such sites also have several serious drawbacks and are in fact rarely suitable for seismic stations. The most important reasons are that:

- existing high towers that sway during windy periods cause high-amplitude, low-frequency seismic noise and may cause large numbers of false triggers with triggered seismic systems and deteriorate low frequency seismic signals. Consequently, a diminished seismic station gain is used resulting in a low detectability of the station;
- there is usually a very high probability of RF interference between seismic RF telemetry system and other users. RF interference may easily impair seismic data transmission and consequently seismic system reliability. Several ‘high power’ parties (compared to one watt or less of RF power used in seismic telemetry) are potentially polluting the RF space at such places. In addition, if other users do not maintain their RF equipment properly, the RF energy radiated within uncontrolled side lobes worsens this danger (this happens quite frequently in developing countries.
- if such sites are inhabited, it is likely there will be too high man-made seismic noise due to human activities);
- the topography of such mountain peaks is rarely suitable for a seismic station. Communication antennae towers usually try to cover an area as large as possible, therefore, as a rule, they are placed on the highest mountains in a country or region;
- nearly all such sites have powerful diesel generators to support communication equipment during power outages. When in operation, these generators are a major source of man-made, high frequency seismic noise. Of course, these generators will surely be running after a strong earthquake because that is precisely when it is most likely that the main power lines will fail. Since the periods during strong earthquakes and following aftershock sequence are the most important for the seismic network, the existing communication towers definitely are not at all suitable for seismic sites.

| Topic   | Recommended minimal distances of seismic sites from sources of seismic noise                                                 |
|---------|------------------------------------------------------------------------------------------------------------------------------|
| Author  | Amadej Trnkoczy (formerly Kinemetrics SA);<br>E-mail: <a href="mailto:amadej.trnkoczy@siol.net">amadej.trnkoczy@siol.net</a> |
| Version | Sept. 1999; DOI: 10.2312/GFZ.NMSOP-2_IS_7.3                                                                                  |

Recommended minimal distances from sources of seismic noise to a seismic site (according to Willmore, 1979) are:

|                                                                                                      |   |                                                   |      |                                                                             |      |                    |      |      |

**LEGEND:**

- A SP seismic station with a gain of about 200,000 or more at 1 Hz
- B SP seismic station with a gain from 50,000 to 150,000 at 1 Hz
- C SP seismic station with a gain of approximately 25,000 or less at 1 Hz
- a Source and seismometer on widely different geological formations or that mountain ranges or valleys intervene
- b Source and seismometer on the same geological formation and with no intervening alluvial valley or mountain range

**Instructions for use of the form:**

1. Get the information about all potential sources of seismic noise around the site and write the distances to them in the extreme right column of the table.
2. From geological maps and by visiting the site decide on the quality of the bedrock at the site. Decide either for 'good' rock (left three columns A, B, and C with minimal recommended distances) or for 'less suitable' ground (right three columns A, B, and C with the minimal recommended distances).
3. For each seismic noise source (where applicable) decide about seismic coupling between seismic site and the noise source. Select the appropriate horizontal line a) or b) with minimal recommended distance.
4. Mark appropriate cells in the table based on the steps #2 and #3 and compare their content with the actual distances in the extreme right column.
5. Shade all cells of the selected A, B, and C columns where the recommended minimal distances to a noise source is bigger than the actual distance in the extreme right column. Find that of the columns A, B, or C where no shaded cells appear. If this is the column A, the site is appropriate for a sensitive SP station having gain 200,000 or more, if this is column B the site is appropriate for a medium sensitive station having the gain somewhere in between 50.000 and 150.000, if it is column C, only a moderately sensitive station with gain around 25.000 or less can be established.
6. Make such a table for all potential seismic sites studied and compare the results among alternatives.

| Topic   | Detectability and earthquake location accuracy modeling of seismic networks                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

This information sheet focuses on the accuracy of determination of earthquake hypocenter location with respect to the locations of seismic stations in a local network and the estimation of network detection thresholds.

Contemporary methods of determination of hypocenter location and earthquake origin time are based on modeling the travel time, which is needed for seismic waves to travel from the hypocenter to the station of a seismic network. For this we need to know:

- location and height above sea level of the seismic stations;
- accurate time on all seismic stations;
- velocity structure of the Earth, through which the seismic waves propagate.

If these parameters are known, we can calculate by means of numerical methods the theoretical travel time of seismic waves from an arbitrary hypocenter to the seismic station. The calculated travel times are then applied to the actual arrival times which were picked from seismograms on all available seismic stations and thus the hypocenter location and earthquake origin time is calculated.

The accuracy of such earthquake locations depends on the three points listed above and on the accuracy of phase picking. Additionally, the theoretical accuracy of hypocenter locations is also controlled by the spatial distribution of seismic stations. Nowadays, with GPS receivers being readily available at reasonable cost, it is not difficult to know the station location and the correct time exactly. The velocity structure of the Earth is fixed, however, and often enough not well known. By studying it, the accuracy of location can be improved. Unfortunately, the determination of the velocity structure requires either extensive specialized deep seismic refraction surveys or an already operating and sufficiently dense seismic network.

Therefore, in the phase of seismic network planning, we can improve its accuracy of event location only by reasonable distribution of the stations.

A computer program LOK has been developed which estimates the accuracy of hypocenter location based on a given spatial distribution of stations. The following assumptions are made:

- station co-ordinates are known exactly;

- for locations of seismic stations an RMS value of noise in the frequency band within which the STA/LTA trigger algorithm will operate (for digital stations) or for the frequency band of the recording equipment (for analogue stations) is known;
- for both digital and analogue stations the frequency response of the seismographs is flat and proportional to ground velocity in the frequency band of interest for modeling the station and network capabilities. This bandwidth depends on the task but also on the network geometry and sensitivity. For local networks it is usually in the range between 1 and 10 Hz;
- P and S arrival times are picked with a known a priori uncertainty (e.g., 0.1 s);
- P and S velocities within the layers and the positions of layer boundaries are known with some known uncertainty;
- travel times are computed for a flat Earth model consisting of homogeneous layers;
- the size of the network area is such that flat Earth approximation can be used.

The results obtained with LOK crucially depend on these assumptions. However, even with poor choice of input parameters (e.g. velocity model) one can get relative performance of different network geometry.

In developing the program LOK we followed mainly the method described in Peters and Crosson (1972). It uses the fact, that the errors of the travel time solution depend on partial derivatives of the travel time function by the unknowns we are looking for. These unknowns are the hypocenter location and the earthquake origin time. The derivatives can be calculated for every point within the seismic network. The area is divided into squares in terms of longitude and latitude. When LOK is run, a hypocenter error ellipsoid is constructed for every grid point. The largest semi-axis of the error ellipsoid is named the hypocenter determination error while the largest of the projections of the ellipsoid semi-axes on the horizontal plane is named the epicentre determination error.

For the computation of the error ellipsoid one should include only stations on which the expected signal is above the noise threshold as defined in the station file (amplification for analogue stations and RMS noise values and STA/LTA trigger ratio for digital stations). Thus the program also gives some information on the differences in expected detectability of events for different geometries of the network. Absolute level of detectability is impossible to predict without detailed knowledge of the attenuation in the region.

Figure 1 below shows the results of respective model calculation for the Stareslo network in Slovenia. The input and output files for this example are included in the distributed version of LOK (see below). An area of  $3.5 \times 1.75$  degree was modeled. An earthquake of  $M_l = 1.0$  was assumed to occur at 15 km hypocentral depth. The network consists of 7 stations, denoted by red triangles in the figure. The border of Slovenia is shown in thick blue. The thin black lines, which are the actual result of the modeling, are isolines of constant hypocenter location error. The numbers in the labels are in kilometers.

As one can see, the error increases outside the network, and the network also has a few blind spots within, where the hypocenter determination error is rather large. The detectability of the network for earthquakes of  $M_l = 1.0$  (at least 4 stations must record the event to obtain the earthquake location) can also be seen. Other examples of magnitude threshold as well as epicenter and hypocenter error calculations using an earlier version of LOK, are shown in Figs. 7.6 to 7.8. of Chapter 7.

The software enables calculation with different hypocenter depths and earthquake magnitudes. It also includes a routine that determines the stations that recorded a particular event. LOK was written in FORTRAN 77 and tested under Linux. The original LOK code has recently been upgraded. A Makefile has been included, written for Intel Fortran Compiler. Users invoke the “make” command in the source directory and LOK is compiled and built. If, however, another compiler is used, the Makefile has to be modified accordingly. Yet, variables were defined in a way that the code does no longer rely on implicit Fortran definition of the variables. For downloading the source code see on the NMSOP-2 cover page in the **Overview** listing *Download Programs & Files* for **lok-sept2011.tar** and related general instructions.

**Figure 1** Result of model calculations for the Stareslo network in Slovenia for  $M_l = 1.0$  earthquake. Red triangles: station positions, blue lines: borders of Slovenia, thin black lines: isolines of hypocenter location error in km; thick black outer boundary: outer limit of the network's location capability for earthquakes of  $M_l = 1.0$ .

## 8.1 Introduction

In this Chapter, a brief description of seismic systems will be given. It is intended to provide an overview on basic ideas in seismometry and describes the existing possibilities in the market (year 2009). This Chapter should be of help during the planning stage of a seismic network. For more thorough information about particular elements and concepts in seismometry and seismic recording systems see Chapters 5 and 6, respectively. Note that this Chapter shares most of the figures and some paragraphs with Havskov and Alguacil (2006). Since one of the authors is the same in both, no related acknowledgment is given.

Before 1960, there were generally only individual seismic stations operating independently. Each station made its observations, which were usually sent to some central location. If several stations were operating in a country or region, it was possible to talk about networks. However the time lag between recording and manual processing were very large compared to modern seismic networks. In the 1960s, seismic networks started operating. These were mainly networks made for microearthquake recording, and the distances between stations were a few kilometers to a couple of hundred kilometers. The key feature used to define them as networks was that the signals were transmitted in real time by wire or radio link to a central recording station where all data was recorded with central timing. This enabled very accurate relative timing between stations and therefore also made it possible to make more accurate locations of local earthquakes. Recording was initially analog and, over the years, it has evolved to be nearly exclusively digital. Lee and Stewart (1981) provide a good general description of the pre-digital transmission networks.

With the evolution of communication capabilities to cover the whole world, seismic networks can now be local, regional or global. The main elements of a modern seismic station are the vault, the seismometer, the digitizer, storage and communication. The distinction between networks is primarily no longer due to differences in data transfer, accuracy of timing, or time lag between data acquisition and analysis, but rather the scope of investigation, spatial resolution, and quality of data in terms of frequency content and dynamic range.

Establishing a new network can be quite challenging and there may be some networks that have not fulfilled their expectations. The main reason for this was probably a lack of knowledge about networks, instrumentation and data processing techniques. Yet such specialized knowledge is unquestionably required if one expects to establish and operate a truly beneficial seismic network. For that reason, in addition to the general description of networks, this document will also outline the basic steps to follow in order to establish a new seismic network.

## 8.2 Seismic network purpose

The main purpose of seismic networks is to determine earthquake locations and magnitudes, to issue alarms, general or specific seismic monitoring and to provide data for research on the interior of the Earth. However, the most basic goal is the determination of accurate earthquake locations. For calculating the three hypocenter coordinates one needs at least the P onset times measured at three stations, or from 4 stations if also the origin time has to be determined as the fourth unknown parameter (see IS 11.1). If, however, the hypocentral distance can be determined for each station independently from the difference of onset times of different seismic phases, e.g., S-P, then 3 stations are generally sufficient (Fig. 8.1). Local, regional

and global research into the Earth's interior is the oldest goal of seismology. Seismic networks are and will be probably forever the only tool that enables study of the detailed structure and physical properties of the deeper Earth's interior.

**Fig. 8.1** Location by the circle (or arc) method. To the left is shown the seismograms at stations S1, S2 and S3 recording a local earthquake. Note that the amplitude scales are different. The stations are located at S1, S2 and S3 (right). The time separation between the P- and S-wave arrivals multiplied by the ratio  $v_P \cdot v_S / (v_P - v_S)$  of the P- and S-wave velocities gives us the hypocentral distance (distance from the station to the earthquake's focus at depth  $h$ ). The epicenter, which is the projection of the focus to the surface, is found within the black area where the circles cross with some “overshoot”. The circles will rarely cross at one point, which indicates errors in the observations, errors in the model, and/or a subsurface source depth. With only two stations, we see that there are either two possible locations, or no possible location if the two circles do not intersect. With more than three stations, the uncertainty in location decreases. Minimization of large circle overshoot can be used to estimate the source depth (see Demo to EX11.1). Note that the “rule-of-thumb” formula given for the distance calculation in the lower right of the figure is for Sn-Pn only. It would be  $8 \cdot (S\text{-time} - P\text{-time})$  for Sg – Pg.

The seismic alarm function, which requires an immediate response after strong earthquakes, serves civil defense purposes with the goal of mitigating the social and economic consequences of a damaging earthquake. Governments, which often finance new seismic networks, emphasize this goal. A related self-organizing seismic early warning information network for Istanbul (SOSEWIN) has been described by Fleming et al. (2009). But seismic monitoring also aides in the long-term mitigation of seismic risk in a region or country as well as in resolving the seismotectonics. Seismic hazard maps of the region may be made which enable the development and implementation of proper building codes. In the long term, building codes are very effective in mitigating seismic risk.

Some cases of seismic monitoring related to seismic risk caused by human activity are of special political concern. This includes monitoring for seismicity induced by large dams or around large mines. Monitoring of seismicity in a volcanic region (see Chapter 13) is also dedicated to volcanic risk mitigation through the prediction of eruptions. Another important function of seismic networks is for explosion monitoring, particularly underground nuclear explosions. Seismic networks are essential to the monitoring of the international nuclear test ban treaty (see Chapter 15).

The purpose of a new seismic network largely defines the optimal technical design for it. Not every design serves equally well for different goals, and many fail completely for some

particular goals. However, modern networks are more capable of dealing with several goals than older networks, which were more narrowly focused due to technical limitations.

## **8.3 Seismic sensors**

### **8.3.1 General considerations**

The choice of an appropriate sensor depends on the application, be it local, regional or global monitoring. The most important factors to consider for a particular application are:

- type of the sensor - accelerometer versus seismometer (compare, e.g., Chapters 11 and 15).;
- number of sensor components per seismic station;
- sensor's sensitivity and dynamic range;
- sensor's frequency range of operation; and
- sensor handling (i.e., how demanding are its transportation, handling, installation, calibration, maintenance etc.; see, e.g. Chapter 7).

### **8.3.2 Seismometers and/or accelerometers?**

During most damaging earthquakes, weak-motion records made with seismometers installed close to the epicenter are clipped. Seismometers are very sensitive to small and distant events and are thus too sensitive for strong-motion signals. This was a very relevant aspect at the time of analog recordings. Traditionally, accelerometers have been considered for strong motion only and seismometers for weak motion. However, the latest generation accelerometers are nearly as sensitive as standard short-period (SP) seismometers down to frequencies around 1 Hz and also have a large dynamic range (up to more than 110 dB; e.g., the Episensor ES-T in DS 5.1). Consequently, for most traditional SP networks, accelerometers would work just as well as 1-Hz SP seismometers and they are similarly priced. At the same time, broadband sensors are now more affordable and have a larger dynamic range. In area where only moderate size earthquakes are expected, broadband seismometers may be sufficient. However, their gain towards higher frequencies (>10 Hz) may be less than for SP sensors. In terms of signal processing, there is no difference in using a seismometer or an accelerometer and correcting digital data for differences in the instrument response can make the signals look identical.

In high seismic risk areas where the main goal of networks is future seismic risk mitigation, strong-motion recordings play an important role, and two sets of sensors will have to be installed so that the system never clips. Although there are significant differences in strong and weak-motion network designs, today both types of sensors are frequently integrated into a single system. Six-channel data loggers with three weak and three strong-motion channels are cost effective and are the current state-of-the-art. They are capable of covering the whole dynamic range of seismic events, from the lowest seismic noise to the largest damaging events. The relative merits of these systems, as well as specific technical details of strong-motion networks, are addressed in the NMSOP\_2 Chapter 7, section 7.4.6 on borehole strong-motion array installations, as well as in several reports and papers of the Consortium of Organizations for Strong Motion Observation Systems (COSMOS), which can be downloaded via the COSMOS website <http://www.cosmos-eq.org>.

### 8.3.3 One- and three-component seismic stations

Historically, many seismic stations and networks used single-component sensors - usually vertical seismometers. Many of them still operate. This was the case because the equipment was analog and the record was often on paper. If three components had been used, three times the amount of equipment would have been required but the information generated would not have been three times more valuable. It was also very difficult, if not impossible, to generate a ground-motion vector from three separate paper seismograms.

Today, in the era of digital recording and processing of seismic data, the situation is different. The price/performance ratio is much more favorable for three-component stations. Most data recorders and data transmission links are capable of accepting at least three channels of seismic data. The cost of upgrading the central processing facilities to accommodate an increased number of channels is relatively small and ground-motion vectors may be generated easily through data processing.

Since ground motion is essentially a vector that contains all of the seismic information, and considering the fact that many modern seismological analyses require this vector as input information, one-component stations are no longer a desirable choice for new installations (not considering seismic arrays which are discussed in Chapter 9). On the other hand, one-component seismic stations are still a choice where communication capability and economy are limiting factors.

### 8.3.4 Sensitivity of seismic sensors

Strong-motion accelerometers are relatively insensitive since they are designed to record the strongest events at small hypocentral distances. Their maximum on scale acceleration is usually expressed as a fraction of the Earth's gravity,  $g$  ( $9.81 \text{ m/s}^2$ ). Accelerometers with 0.25, 0.5, 1, 2, and 4  $g$  full-scale sensitivity are available today. However, modern accelerometers have excellent dynamic range and good signal resolution. They will produce valuable records of smaller events within the close-in epicentral region as well, where seismometer records may still be clipped unless a high-dynamic range recording system is used. Of course, one should order full-scale sensitivity, fitting to the maximal expected acceleration at the sites of the new network. Ordering too sensitive accelerometers may result in clipped records of the strongest and most important events in the region. Accelerometers with too high full-scale range cause diminished sensitivity and needlessly reduce data acquisition resolution of all future records. If the network only uses accelerometers, the most sensitive must be used in order to record small earthquakes if the purpose of the network is not exclusively strong motion.

Weak-motion sensors - seismometers - are usually orders of magnitude more sensitive, however, they can not record as large an amplitude as an accelerometer. They can record very weak and/or very distant events, which produce ground motion of comparable amplitudes to the background seismic noise. Some seismometers can measure ground motion smaller than the amplitudes of the lowest natural seismic noise found anywhere in the world. If one plans to purchase especially sensitive sensors, one must be willing and able to find appropriate, low seismic noise sites for their installation. Standard SP seismometers are in fact so sensitive that they will be able to resolve the ambient Earth's noise above 0.5 Hz in nearly all networks where they are installed. The self-noise of broadband seismometers is typically lower than the

Earth noise down to 0.01 Hz. If the sites are not appropriately chosen and /or have high seismic noise (natural and/or man made), a modern, highly sensitive seismometer is of little use, and a much cheaper sensor, like an accelerometer or a geophone, might be used. However, generally due to affordability and capabilities in terms of frequency and dynamic range, broadband instruments are becoming the standard.

### 8.3.5 Frequency range of seismic sensors

Today's weak-motion sensors are roughly divided into three categories.

The short-period (SP) seismometers measure signals from approximately 0.1 to 100 Hz, with a corner frequency at 1 Hz. They have a flat response to ground velocity for frequencies greater than this corner frequency. Typical examples are the Kinometrics SS-1, the Geotech S13, and the Mark Products L-4C. The 4.5-Hz exploration-type geophone also belongs in this group. This sensor provides reasonably good signals down to about 0.3 Hz at a fraction of the cost of the 1.0-Hz sensor.

Broadband seismometers (BB) have a flat response to ground velocity from approximately 0.01 to 50 Hz. Typical examples are the Guralp CMG3T seismometer with frequency range from 0.008 to 50 Hz, the Wieland-Streckeisen seismometer STS2 with a frequency range from 0.008 to 40 Hz and the similar Chinese CTS-1 (see DS 5.1).

The very broadband seismometers (VBB) can resolve amplitudes of frequencies from below 0.001 Hz to approximately 10 Hz. The best performance at low frequencies is given by the Wieland-Streckeisen STS1 seismometer with frequency range from 0.0028 to 10 Hz (no longer produced). The Chinese JCZ-1 operates in an even wider range from 0.0028 to 50 Hz. However, also the Nanometrics Trillium, the Guralp CMG3T and the STS2 can, proper installation and shielding provided, resolve signals with frequencies below 0.001 Hz (see 5.5.3, 5.5.4, 7.4.4., DS 5.1 and IS 7.5). They are all able to resolve Earth's tides.

On all these different seismometers more information is given in DS 5.1.

The frequency limits shown above are the corner frequencies of the seismometer response functions. This means that analysis below the low-frequency corner and above the high-frequency corner is usually still possible, however, with reduced gain. How much we can extend this range depends on the sensor design, the instrumental self-noise (see Chapter 5, sections 5.5.5 to 5.5.7), the signal-to-noise ratio and beyond the upper corner frequency also on the sampling rate and the steepness of the anti-alias filter (see Chapter 6). The choice of the right sensor depends on its seismological application. In general, the flat portion of the frequency response function should cover the relevant range of frequencies in terms of displacement, velocity or acceleration amplitudes of interest in the investigation of a particular type of seismic event or seismic effect (see Fig. 5.3).

Strong-motion sensors (accelerometers) measure seismic signals between DC and 200 Hz (a typical example is the Kinometrics' EpiSensor; see DS 5.1). However, they differ from the weak-motion sensors in that their output voltage is proportional to ground acceleration and not to ground velocity as it is usual for modern feedback-controlled broadband seismometers. For this reason, as compared to seismometers, accelerometers emphasize high frequencies and reduce low frequency amplitudes. Some strong-motion sensors in the market have no DC

response but a low-frequency, high-pass corner at around 0.1 Hz. These sensors have an important drawback: their records can not be used for residual displacement determination, either of the ground in the near field of very strong earthquakes, or of permanently damaged civil engineering structures after strong events. They are considered as less appropriate for seismic applications where low-frequency signals are important too. The following table should help in the selection of appropriate sensors. It shows some typical seismological applications and their approximate frequency range of interest.

**Tab. 8.1** Application description and approximate frequency range of interest.

| <b>Application</b>                                           | <b>Frequency range (in Hz)</b> |
|--------------------------------------------------------------|--------------------------------|
| Seismic events associated with mining processes              | 5 - 2000                       |
| Very local and small earthquakes, dam induced seismicity     | 1 - 100                        |
| Local seismology                                             | 0.2 - 80                       |
| Strong-motion applications                                   | 0.0 - 100                      |
| General regional seismology                                  | 0.05 - 20                      |
| Frequency dependence of seismic-wave absorption              | 0.02 - 30                      |
| Energy calculations of distant earthquakes                   | 0.01 - 10                      |
| Scattering and diffraction of seismic-waves on core boundary | 0.02 - 2                       |
| Studies of dynamic processes in earthquake foci              | 0.005 - 100                    |
| Studies of crustal properties                                | 0.02 - 1                       |
| Dispersion of surface waves                                  | 0.003 - 0.2                    |
| Free oscillations of the Earth, silent earthquakes           | 0.0005 - 0.01                  |

### 8.3.6 Short-period (SP) seismometers

The SP sensors were historically developed as 'mechanical filters' for mitigating distracting natural seismic noise in the range 0.12 - 0.3 Hz. This noise heavily blurred small events on paper seismograms. However, with today's digital and high-resolution data recording and processing, this rigid 'hardware' filtering can easily be replaced by much more flexible signal processing. A need for sensors that filter seismic signals by themselves does not exist anymore. In addition, when filtering the seismic signal with sensors, we irreversibly lose a portion of seismic information and introduce undesired signal phase distortion. Nevertheless, the SP seismometers, as well as the cheaper geophones, are still a valid selection for several seismological applications, particularly for local seismology where low frequencies of seismic signal are not of major interest or do not exist at all. The traditional 1 Hz sensor might however disappear due to high construction cost compared to modern active sensors.

Most SP electromagnetic seismometers (EDS) are passive sensors with a flat response to velocity above the natural frequency. They are easy to install and operate and require no power, which allows use of smaller backup batteries for the rest of the equipment at remote station sites. They are relatively stable in a broad range of temperatures, which allows less adjustment (and inexpensive) vault designs. The electronic drift and mass position instability usually associated with active sensors are typically not a problem. They are, in short, a very

practical solution for all applications where seismic signals of interest are not expected to contain significant components below 0.1-0.3 Hz.

There are also active SP seismometers in the market, which are either electronically extended 4.5-Hz geophones or accelerometers with electronically generated velocity output. These sensors are often cheaper and smaller. Their drawback is that they require power and are more complicated to repair. An example of such a seismometer is the Lennartz LE-1D.

### **8.3.7 Broadband (BB) seismometers**

Today, the broadband seismometers are a very popular choice. They provide complete seismic information from about 0.01 Hz to 50 Hz and therefore allow a much broader range of studies than the SP records. Even if the prime objective of a network is to locate earthquakes that could be done with SP sensors, other usage of the data in scientific studies benefits from BB sensors.

However, the BB seismometers demand more efforts for installation and operation than SP seismometers. The BB seismometers require a higher level of expertise with respect to instrumentation and analysis methods. They are active feedback sensors and require a stable single- or double-polarity power supply. They also require very careful site selection in a seismological-geological sense as well as a better-controlled environment in seismic vaults in order to benefit from the low frequency part of their output ( $< 0.1$  Hz). Older models are sometimes a bit tricky to install while newer models require less adjustments. Since they do not attenuate the 0.12 - 0.3 Hz natural seismic noise peak (see Fig. 4.7), their raw output signal contains much more seismic noise than signals from a SP seismometer. Consequently, useful seismic signals are often buried in seismic noise and can be resolved and analyzed only after filtering to remove the background noise. So, for all but the largest earthquakes, filtering is required even for making simple phase picks. BB sensors are often perceived as the 'best choice', however at high frequencies ( $> 50$  Hz) their gain is typically less than for SP sensors, and for example for microseismic monitoring the SP sensors will be a better choice.

### **8.3.8 Very broadband (VBB) seismometers**

The VBB seismometers are utilized in global seismology studies. They are able to resolve the lowest frequencies resulting from Earth's tides and free oscillations of the Earth. Their primary purpose is the research of the deep interior of the Earth. Their only important advantage, however, as compared to BB seismometers, is their ability to record frequencies around and below 0.001 Hz. They are expensive, require very elaborate and expensive seismic shelters, and, as a rule, are tricky to install. They are ineffective for seismic risk mitigation purpose and some also lack frequency response high enough for local/regional seismology.

However, data from a VBB station are very useful to the international scientific seismological community. They are also excellent for educational purposes. For a large national project, installation of at least one VBB station is recommended and perhaps two to three in a very large country or region. Site selection and preparation for a VBB station requires extensive study and often expensive civil engineering work (e.g., Uhrhammer et al., 1998 and 7.4.4). The cost of preparation of a single good VBB site can exceed US\$ 100,000.

### 8.3.9 Long-period (LP) passive seismometers

The long-period passive sensors are not a suitable choice for new installations and are not sold anymore. These sensors have a corner frequency of 0.05 to 0.03 Hz and, in that respect, are inferior to most (but not all) BB sensors. Their dynamic range is in the order of 120 dB. An LP sensor with a 24-bit digitizer still makes an acceptable low-cost BB station provided the sensors and the vault are already available. However, nonlinear distortion of such an installation may be problematic. Nevertheless, in the scope of new installations, long-period seismometers are of historical value only. Instruments based on the traditional design are becoming a popular choice for education in school seismology projects.

## 8.4 Seismic network configuration

### 8.4.1 Real and virtual seismic networks

When the hardware connection among seismic stations is established, the next question is how the data are sent along the connection and what protocols are used for the units to communicate. This will define, to a large extent, the functionality of the seismic network.

In the days of only microearthquake networks and one-way data transmission (from stations to central-recording site), it was quite clear how a seismic network was defined. Today, the situation is more complex. Nowadays, more and more seismic stations are connected to the Internet and data is available from world-wide distributed stations in near real-time. The stations usually also have a local recording capability. Typically, acquisition, communication and storage is provided by a single unit. Seismic networks are now mostly of this type of stations and the distinction between local, regional, and global networks does not exist any more in terms of hardware, data transmission and acquisition, but is merely a question of how the data are processed.

Due to the improvements in global communication which allows for easy access to data from around the world, the concept of virtual networks has emerged. The term virtual merely indicates that not all stations in the network belong to a single operator or a “real” network. In practice, most networks are virtual. Access to data from a station by another operator could be directly from the station, but often the data is received from the central system. However, in practice it makes little difference in the way stations are connected into either “real” or virtual networks. Examples of virtual networks are the Virtual European Broadband Seismic Network (VEBSN; see <http://www.orfeus-eu.org/Data-info/vebsn.html>), the GEOFON Extended Virtual Network (GEVN-GEOFON; see <http://www.gfz-potsdam.de/geofon/>) the Global Seismographic Network stations and arrays (code \_GSN), the Federation of Digital Broad-Band Seismograph Networks stations (\_FDSN). The “\_” in front of the network code stands for virtual but many national networks become virtual by including data from stations by another operator within or outside the country. Examples of “real” networks are the Global Seismograph Network (GSN - IRIS/IDA) (code II) and the GEOSCOPE network code (G).

As most networks today are virtual networks, it will be assumed in the following that a network is virtual unless specifically noted otherwise.

**Fig. 8.2** Example of a real seismic network. The sensors are connected to a central recorder through a permanent connection like a wire or radio link. The latter may also be via satellite when the network covers large territories. The transmission may be analog with digitization taking place centrally, or an analog-to-digital converter (ADC) could also be placed at each sensor and the data transmitted digitally.

**Fig. 8.3** Example of a virtual seismic network. The thick line is the communication network, which can have many physical implementations. The data collection computer collects data from some or all of the recorders connected to the network. This network could also be a real network if all stations belonged to a single operator.

## 8.4.2 Seismic networks

### 8.4.2.1 Stand-alone and central-recording based seismic systems

In the simplest case, a seismic network is a group of stand-alone seismic stations with a local recording medium. Many of the older networks, particularly analog ones, are still of this type. The information is gathered in person, either by collecting paper seismograms or by locally downloading digital data from stations into a laptop computer. There exist no communication links from the remote stations to the data center. Data can be stored locally on a removable memory medium like memory cards, or removable hard disk. Temporary networks are typically deployed in this way. Such networks can either record in continuous mode or in triggered mode. Earlier, triggering mode was the most common due to limitation in the storage capacity, while today, continuous mode is the most common. Triggering mode is now mostly used in strong-motion seismology where recordings are rare. As a permanent, national, or regional observatory seismic network, this design is rarely suitable.

Most modern networks involve near real-time data transfer from the remote stations to the central processing site. The real-time data can be received over a radio link, satellite or some form of Internet communication. It is quite common to have various means of communication within one network. Data is received by the client at the receiving end from the server at the field stations or another data centre. Most such networks now store continuous data. At present, most networks operate in this fashion. There can be a trade-off between the indispensable remoteness of the seismic stations and the availability of a communication link. However, satellite and possibly mobile phone based solutions are applicable in remote locations. It is also possible to bridge the distance to a point with permanent communication using short-distance spread spectrum RF links.

Most real time networks have a central trigger function and can, therefore, use coincidence detection algorithms in near real time (see 8.5.2).

It is common that networks use more than one system to acquire and process the data. It is also possible that some seismic stations are linked, but not sending data in real-time. It is, therefore, often necessary to make use of software that combines the different systems into one, and brings the data onto a single platform for interactive data processing.

The decision on which type of network to use depends on the availability of communication and the requirement for alarm functionality. For seismic networks with the exclusive purpose of monitoring general seismicity and/or to serve research purposes, there is no need for real-time data. The two main factors in deciding which network is the most appropriate are cost of ownership and quality of data. For research purposes, flexibility is also a very important issue. If an Internet based system is available at seismically quiet sites, this may be the least expensive way to construct a network. Since communication costs are quickly decreasing and links are becoming universally available, real-time networks are now most common.

#### **8.4.2.2 Examples**

*Example 1:* IRIS is the largest global data centre and receives 1,000s of seismic channels in near real-time. The Global Seismograph Network (GSN) itself consists of more than 150 stations. The remaining data is provided by other networks from around the globe. Subsets of the data are combined into virtual networks, such as the GSN and FDSN networks. Data are made freely available as continuous near-real time data streams, or on request as continuous data files and event-based data sets. Very importantly, the GSN is currently re-equipped (completed by 2013) with standardized data collection systems based on the Quanterra Q330HR (high resolution) systems and has embarked on supplementing the yearly relative calibration procedures by network operators' in situ calibrations with portable equipment, thus verifying sensor and system responses as well as sensor orientation and location. Moreover, complete instrument description is available for all data. A number of mechanisms are supported to provide the data. (<http://www.iris.edu/data/request.htm>). The real-time data is made available through LISS and SeedLink (see 8.6.4 and Chapter 10) and event data through tools such as Wilber, BreqFast and WebRequest. Fig. 8.4 shows the GSN network and Fig. 8.11 the type of communications used.

*Example 2:* The public domain SEISNET system is another software enabling establishment of semi-real time virtual seismic networks. SEISNET operates with other types of stations in addition to the GSN stations and also performs network detection and preliminary location

(Ottemöller and Havskov, 1999). It was developed for the Norwegian National Seismic Network and is also used in several other places. SEISNET is very flexible and can be adopted for virtually any type of field station.

*Example 3:* Another widely used and publicly available software is EARTHWORM (EW) (runs on Solaris, Linux, Mac OS X, and Windows), also see <http://www.isti2.com/ew/> . It allows users to run real-time seismic networks of different purpose with emphasis on either real-time seismic data processing or data storage and user interaction. EW includes real-time data transport, automated event detection, phase picking, seismic event association and location, archiving, and other modules, and was originally developed by the U.S. Geological Survey's (USGS) Northern California Seismic Network (NCSN). EW is used by a world-wide community of ~150 institutions that operate the system or its derivatives and contribute to its development and maintenance. Instrumental Software Technologies, Inc. (ISTI) coordinates and leads this worldwide effort. EW modules are also used in other software systems such as HYDRA, used by NEIC, Earlybird used at the Alaska Tsunami Warning Center, and ANSS Quake Monitoring System (AQMS) used by the ~450-station NCSN, the ~400-station SCSN California networks, five other ANSS funded US regional networks, as well as by many other earthquake and volcano networks world-wide.

*Example 4:* The proprietary ANTELOPE software is yet another real-time seismic network software package on the market. It supports a wide range of seismic stations as well as other environmental monitoring equipment. ANTELOPE's open-architecture, modular, UNIX-based, real-time acquisition, analysis, and network management software supports all telemetry using either standard duplex serial interfaces or standard TCP/IP protocol over multiple physical interfaces. In addition to data acquisition, the seismic network functionality includes real-time automated event detection, phase picking, seismic event association and location, archiving, system state-of-health monitoring, interactive control of remote stations, automated distribution of raw data and processed results, batch mode seismic array processing and a powerful development toolkit for system customizing. It can handle continuous and event file-based data and uses relational database management formalism and the CSS v. 3.0 scheme for information organization. It runs on Sun Microsystems' Solaris OS on SPARC and Intel architectures. It was developed by the BRTT Company and Kinemetrics Inc. and is currently used by IRIS networks, the US Air Force, several seismic networks in the US, and about eight national seismic networks in Asia and Europe.

*Example 5: Geofon network.* The most used software in Europe is the public domain SeisComp – SeedLink system developed by GFZ (German Research Centre on Geosciences in Potsdam) (see <http://geofon.gfz-potsdam.de/geofon/seiscomp/> and <http://www.seiscomp3.org/>) and the largest network using this software is the global GEOFON network consisting of GFZ stations and cooperating stations in other countries (see Fig. 8.5). The stations in the GEOFON network all send their data in real time to the GFZ in Potsdam. Rapid global earthquake information has recently become a major task of the GEOFON Program. E.g. GFZ is a key node of the European Mediterranean Seismological Centre (EMSC) and has the responsibility for rapid global earthquake alerts. The GFZ became also a leading force in earthquake monitoring for tsunami warning using SeisComp in the Mediterranean and the NE Atlantic as well as for the Indian Ocean.

# GSN & FEDERATION OF DIGITAL BROADBAND SEISMIC NETWORKS (FDSN)

**Fig. 8.4** The Global Seismic Network (GSN) and other global broadband stations that are members of the Federation of Digital Broad-Band Seismograph Networks (FDSN) (figure from IRIS home page <http://www.iris.edu>).

**Fig. 8.5** The GEOFON network. Figure from <http://geofon.gfz-potsdam.de/geofon/>

## **8.5 Seismic data acquisition and data processing**

### **8.5.1 Digital versus analog data acquisition**

There exist three primary types of physical seismic networks with respect to the technology of data acquisition: analog, mixed, and digital.

#### **8.5.1.1 Analog seismic systems**

The analog seismic systems include sensors, which are always analog, analog signal conditioning, usually frequency modulated (FM) telemetry through radio (RF) or phone lines, analog demultiplexers, and analog drum or film recorders. Paper or film seismograms are the final result of a completely analog system. Analog systems have serious drawbacks and are no longer built. The low dynamic range and resolution of the acquired data (about 40-45 dB with single and about 60-65 dB with double, low and high-gain data transmission channels) lead to issues of incomplete data. On the one hand, many events have amplitudes that are too low to be resolved on paper or film records, while on the other hand, many records are clipped because their amplitude is too large for undistorted recording. In fact, only a very small portion of the full dynamic range of earthquakes that are of interest to seismologists are actually recorded distortion free on analog systems. Another problem is the incompatibility of paper and film records with computer analysis. This is a very serious drawback today because modern seismic analysis is almost entirely based on computer processing.

#### **8.5.1.2 Mixed analog/digital systems**

Mixed systems, frequently erroneously called digital, have analog sensors, analog signal conditioning, usually FM telemetry, and analog demultiplexers, but digital data acquisition at the central-recording site, digital processing, and digital data archiving.

Such systems also have a low dynamic range (usually FM data transmission links are the limiting factor) and therefore, they have the same disadvantage as the analog systems regarding data completeness and quality. However, they can accommodate off-line as well as automatic near-real time computer analysis. One can use most modern analysis methods, except those that require very high-resolution raw data. Such systems are still useful for some applications when the higher dynamic range of a fully digital system is not of prime importance and the purpose of the seismic network is limited to a specific goal. Advantages of these systems include low cost and low power consumption of the field equipment. Fig. 8.6 shows a typical setup. Many systems are still running, but no new ones are built.

**Fig. 8.6** Typical analog-digital network. The analog data is transmitted to the central site over fixed analog communication channels, usually FM modulated radio links or phone lines. At reception, the signals are put into a distribution panel where incoming signals are demodulated. Some filtering may take place before the data are digitized by a PC or similar recording system. Timing is done within the digital system. Today, very few alternatives to GPS exist.

### 8.5.1.3 Digital seismic systems

In digital systems, only the seismometers are analog. All other equipment are digital. The dynamic range and the resolution are much higher than that of analog and mixed type systems. These factors depend mainly, but not only, on the number of bits of the analog-to-digital (A/D) converter. 16- to 24-bit A/D converters are available today, which correspond to dynamic ranges of approximately 90 to 140 dB. In practice, however, the total dynamic range and the resolution of data acquisition is usually less than the number of bits an A/D converter would theoretically allow, since 24-bit converters rarely have a noise level as low as 1 bit. Nearly all A/D converters sold now are of 24 bit type. Fig. 8.7 shows a typical setup of a digital seismic network.

**Fig. 8.7** Typical digital network. The digital data is transmitted to the central site over fixed digital communication channels. At reception, the signals enter the recorder directly. Timing normally takes place at the field stations, although some systems also time stamp the signal on arrival.

Buyers of digital seismic networks sometimes ask for additional paper drum recorders because they wish to continuously monitor incoming signals and/or believe drum recorders will serve as an excellent educational tool. However, there are a number of problems with paper drum recorders in digital systems. One problem revolves around the requirement for additional electronic components, such as digital to analog converters. Being mechanical devices, drum recorders are and will continue to be expensive, often costing more than a multi-channel digital recorder. They require continuous and specialized maintenance and consumables. On the other hand, nearly all modern observatory seismic software packages allow for the continuous, near-real-time observation of the incoming signals and some even simulate the traditional appearance of paper helicorder records. Once a user becomes familiar with a digital system, expensive paper drum recorders soon prove to be of little use and are thus a poor investment.

## 8.5.2 Trigger algorithms and their implementation

### 8.5.2.1 Continuous versus triggered mode of data acquisition

Continuous, digitally-acquired seismic signals by their very nature provide a large amount of data. A reasonably sized, digital, weak-motion seismic network operating in continuous mode will produce a large volume of data. In the past, due to limited storage capability, only the event data was stored. However, now this is no longer a problem and all data can be stored. Recent studies make use of continuous noise recordings, which shows that what previously was considered useless data can now provide valuable results (see Chapter 14). With modern networks it is no longer a question and continuous data must be stored.

The storage problem had frequently led seismic network users to operate their systems on a "triggered" basis (particularly the local and regional seismic networks that require a high frequency of data sampling). Triggered only systems still do continuous, real-time acquisition

and processing of seismic signals, but only store signals associated with seismic events. Such systems do not store continuous time histories of seismic signals, but rather produce "event files". Obviously, systems in triggered mode will lose some weak events and produce a certain number of false triggers. The completeness of data inevitably is impaired because the efficiency of the trigger algorithms currently available is inferior to the pattern recognition ability of a trained seismologist's eye.

The continuous seismic signal recording provides the most complete data, but processing and storage of all data can be difficult and expensive. Continuous recording can be achieved through the use of a ring-buffer system, where a fixed size is allocated to the data and the oldest data is overwritten by the newest. Some systems simply write data files and remove the oldest files when the storage capacity is reached. Most systems now record continuously and run a trigger algorithm only to produce detection lists. However, strong-motion systems typically still operate in triggered mode.

#### **8.5.2.2 Trigger algorithms**

The trigger algorithms used on a seismic recorded or in a central processing system are basically the same.

The amplitude threshold trigger simply searches for any signal amplitude exceeding a preset threshold. A detection is made whenever this threshold is reached. This algorithm is normally used in strong-motion seismic instruments, which are systems that do not require high sensitivity. Consequently, man-made and natural seismic noise will only produce infrequent triggers.

The root-mean-square (RMS) threshold trigger is similar to the amplitude threshold algorithm, but the RMS value of the amplitude in a short time window is used instead of 'instant' signal amplitude. It is less sensitive to spike-like, man-made seismic noise, however it is rarely used in practice.

The ratio of the short-time average to the long-time average (STA/LTA) of the seismic signal is the basis of the most frequently used trigger algorithm in weak-motion seismology. It continuously calculates the average values of the absolute amplitude of the seismic signal in two consecutive moving time windows. The short-time window (STA) is 'sensitive' to seismic events, while the long-time window (LTA) provides information about the temporal amplitude variation of seismic noise at the site. When this ratio exceeds a preset value (usually set between 4 and 8), an event is 'declared'. The STA/LTA trigger algorithm is well suited to cope with slow fluctuations of natural seismic noise. It is less effective in situations where man-made seismic noise of a bursting or spiky nature is present. At sites with high, irregular, man-made seismic noise, the STA/LTA trigger usually does not function well. For more details on STA/LTA algorithm and parameter setting see IS 8.1.

Several more sophisticated trigger algorithms are known from the literature. They are sometimes used in seismic networks but rarely in the seismic data loggers available on the market. In the hands of an expert they can significantly improve the event detections/false triggers ratio, particularly for a given type of seismic event. However, these triggers often require sophisticated parameter adjustments that can prove to be unwieldy and subject to error.

Every triggered seismic system must have an adjustable band-pass filter in front of the trigger algorithm. This is particularly important with BB and VBB seismometers where small earthquake signals are often buried in dominant 0.2-0.3 Hz seismic noise. The adjustable band-pass filter allows the trigger algorithm to be sensitive to the frequency band of one's interest. In this way such events may be resolved and acquired. Some recorders allow several trigger sets to be used simultaneously. This is needed if for example, a BB station has to trigger on microearthquakes, teleseismic P waves and surface waves which each require separate setting of filters, STA and LTA. The GSN Quanterra stations operate in this way.

### **8.5.2.3 Coincidence trigger principle**

In seismic networks with standalone stations, each remote station has its own independent trigger. In such networks data are usually transferred to the central-recording site on request only or it is collected in person. These seismic networks have the lowest effectiveness of triggering and consequently, the smallest detection threshold and/or the highest rate of falsely-triggered records. The completeness of data is modest because not all stations in the network trigger simultaneously for each event. This approach requires a good deal of routine maintenance work in order to "clear" numerous false records from the local data memory if trigger thresholds are set low; if not, the network has a lower detection threshold. Remote stations may encounter 'memory full' situations due to having a limited local memory. Such networks absolutely require the careful selection of station sites with as low as possible man-made seismic noise. If low noise is not assured, an observatory quality network may be so insensitive as to be considered a serious project failure. However, such networks are frequently used as temporal seismic networks. They also function well where high sensitivity is not desired at all, for example, in most strong-motion networks.

Seismic networks that use the coincidence trigger algorithm are much better at detection thresholds and completeness of acquired data. In these systems, data are transmitted continuously from all remote stations to the central-recording site where a complex trigger algorithm discriminates between seismic events and seismic noise. The coincidence trigger takes into account not only signal amplitudes but also correlation in space and time of the activated stations within a given time window (the window allows for wave propagation). The trigger threshold level of such a robust algorithm can be significantly lowered, resulting in a more complete record of small events for the entire network. All stations in the network are recorded for every trigger, which greatly improves completeness of the recorded data.

## **8.6 Seismic data transmission**

### **8.6.1 General considerations**

While data transmission may not seem like an important technical issue for a seismic network, a poorly selected or designed data transmission system is one of the most frequent causes for disappointment and technical failures. The success of a seismic network operation rests largely on the reliability and the quality of data transmission, whether by dedicated lines or by internet.

Another very important but frequently overlooked factor is the cost of data transmission. In fact, these costs may largely determine the budget for a long-term seismic network operation. Many seismic networks all over the world have been forced to change to less expensive modes of transmission after some years of operation. The data transmission costs per year in a network established right after a damaging earthquake may seem completely acceptable at first, but may be viewed as excessive after just a few years of relative seismic quiescence. However, communication is becoming easier and cheaper and this should no longer be an issue.

There are some key technical parameters to consider in designing a data transmission system:

- the required information flow (channel bandwidth for analog links or data transfer rate with digital links);
- the distance to which data must be transmitted;
- the desired reliability (acceptable down-time of the links, that is, the maximum time period per year when the signal-to-noise ratio is lower than required (analog links) or bit error rate is higher than allowed (digital links).
- the communication system which will be used to establish the seismic network (Internet, proprietary WANs (Wide Area Networks), analog public phone network, ISDN, ADSL etc.); and
- the protocols that will be used.

These parameters must fit the available data transmission infrastructure in the country or region, the available network operations budget, and the network's performances goals. Technical considerations, reliability, initial price and operational costs of data transmission links vary widely from country to country. Local conditions in a particular country or region are a very important factor in the selection of an appropriate data transmission system. It is essential to get information about the availability, reliability and cost of different approaches from local communication experts.

### **8.6.2 Types of data transmission links used in seismology**

In seismometry there are several different kinds of data transmission links in use, from simple short-wire lines to satellite links. They differ significantly with respect to data throughput, reliability of operation, maximum distance, robustness against damaging earthquakes, and cost of establishment and operation. A table in IS 8.2 enumerates the most common types, their major advantages and drawbacks, and their potential applications.

Note that strong-motion seismic networks generate far less data than weak-motion networks and therefore, their design might differ significantly. Seismic data transmission links that are fully acceptable for strong-motion data may be inadequate for weak-motion data and data transmission links used in the weak-motion field may be an absolute overkill and too expensive for strong-motion networks.

### **8.6.3 Simplex versus duplex data transmission links**

There are two basic types of digital data transmission links.

Simplex links transmit data only one-way, from remote stations to the center. These links are relatively error prone. Radio interference or fading may corrupt data during transmission and there is no way of recovering corrupted data, unless forward error-correction (FEC) methods are used (see 8.8.6.6). However, the FEC methods are rarely used except for satellite links. They require a significant bandwidth overhead, which is hard to provide using standard, low cost 3.5-kHz bandwidth RF channels. Simplex links usually use the type of error-checking that allows recognition of corrupted data but not its correction. The methods in common use range from a simple parity check or check-sum (CS) error detection to cyclic redundancy check (CRC) methods.

Duplex links allow data flow in both directions – from the remote station to the center and vice versa. Different types of error-checking methods are used, ranging from a simple parity check or CS error detection to CRC error detection. Once an error is detected, the data block is resent repeatedly until it is received correctly. In this way, a very significant increase of reliability of data transmission is achieved. Duplex is the standard with modern equipment and communication. However, duplex radio links nearly double the amount of the equipment and are therefore expensive compared to the simplex links.

Today, no commercial networks using simplex are constructed.

### **8.6.4 Protocols for continuous data transmission**

The majority of new networks and many old networks will now record continuously and this has resulted in de facto standards emerging from major operators. The first protocol was LISS (Live Internet Seismic Server, <http://www.liss.org/>) made by USGS and used on the GSN stations (see Fig. 8.8). The protocol sends 512 byte blocks of MiniSEED data on a socket and application on the receiver side can open a corresponding socket and continuously receive the data. LISS has the drawback that if data is lost, there is no way of requesting data since it is just a one way transmission.

This problem has been solved using the SEEDLink protocol that is implemented within the SEEDLink software (Heinlo and Trabant, 2003). This protocol is the same as LISS with an additional data block containing information about transmission status and request information. SEEDLink can therefore request missing data blocks which also makes it possible to request data back in time. SEEDLink is the most used public standard with retransmission and data from large data centres such as IRIS and ORFEUS can be received from their SEEDLink servers. Other real-time data processing systems such as Earthworm come with data exchange protocols. Another widely used protocol is CD1 developed for the International Monitoring System of the CTBTO. In addition, all major seismic equipment companies have developed their proprietary protocols for real-time data exchange, but they may also support the open standards.

**Fig. 8.8** LISS stations (red dots) April 3, 2009. The map shows seismograph stations which are transmitting their data live, via the Internet, to the Albuquerque Seismological Laboratory ([http://aslwwww.cr.usgs.gov/Seismic\\_Data/telemetry\\_data/map\\_sta\\_eq.shtml](http://aslwwww.cr.usgs.gov/Seismic_Data/telemetry_data/map_sta_eq.shtml)). The live data can be seen interactively by pressing the red dot.

### 8.6.5 Data transmission protocols and some examples of their use

Serial data communication and Ethernet are the most commonly used ways to transmit digital seismic data.

Most seismic digitizers will send out a stream of data in serial format and all computers have hardware and software to communicate with serial data. A serial line requires at least 3 lines: One for sending data, one for receiving data, and ground. If data only is to be sent or received, two lines suffice. The serial lines use either RS-232 protocol or the RS-422 protocol. The former can run on up to 50 m long cables and the latter on cables up to 2 km long. Serial line communications may be used by modems, radio links, fixed telephone lines, cellular phone, and satellite links.

*Example 1:* An example of one-way continuous communication (see Fig. 8.9), a remote station has a digitizer sending out RS-232 data, which enters a radio link to a PC, which reads the data and processes it. The communication is governed by the RS-232 protocols. Data acquisition system is done on the PC.

**Fig. 8.9** One-way communication from a remotely installed digitizer via a digital radio link to a centrally located PC. The radio modem and transmitter /receiver might be one unit.

*Example 2:* Interactive communication with a remote seismic station (see Fig. 8.10). A user calls up a terminal emulator on his PC, connects to a modem with one of the PC's serial lines, dials the phone number of the modem connected to the remote station, and logs into the field station. Once logged in, several options are usually available. One is to browse a log file containing all triggered events in the local memory of the station. Another option is to initiate a download of event data. A very common way to do this over a serial line connection is to list the event file in ASCII form and then set up the terminal emulator at the local PC to capture the data. This is one way of getting data from a standard GSN seismic station. The advantage of this type of communication is that only very simple software is required and it is easy to access to many different seismic stations. This process can also be easily automated (see IS 8.3).

**Fig. 8.10** Manual dial-up to a seismic station for data inspection and/or download. The dialing computer can be of any type as long as a terminal emulator program, such as Hyperterminal in MS Windows, is available.

*Example 3:* Interactive communication with a remote seismic station using proprietary software. The user starts up a manufacturer-supplied program on his local PC. The program handles all the communication to the field station purchased from this manufacturer. The user's connection with the field station will be as if sitting next door. Data download, acquisition parameter settings, system state-of-the-health verification, and diagnostic commands (if applicable) are managed through simple menus, and the event files may be automatically transferred to the user's local PC. The process can be run manually or in an automatic, unattended mode at specified times. With some systems, remote stations can initiate the transfer of triggered seismic events. The advantage with this setup is that communication with a particular remote station is very easy. Unfortunately, most of the software systems in the market work only with one type of seismic station.

In high-speed local area networks, Ethernet most commonly connects computers. This low-level protocol is not what the user sees directly, but rather a high-level communication

protocol working on top of the Ethernet protocol. TCP/IP is the most widely used protocol for file transfer and remote log-in. This is also the protocol used by the Internet although the low-level protocol used between the different Internet nodes might not be Ethernet. TCP/IP can also be used over serial lines and ISDN telephone lines. Today, most seismic recorders are able to communicate via TCP/IP protocol. A remote seismic station, which can be reached by TCP/IP either through Internet, satellite, ADSL, ISDN, or regular phone lines, represents the most general purpose and flexible system available.

Fig. 8.11 shows the most common way of establishing TCP/IP connections to a central data collection system. Dashed lines between routers indicate that the connection is made to one station at a time. Large central routers that can communicate with many ISDN nodes at the same time are also available.

**Fig. 8.11** Different ways of getting a TCP/IP connection to a central data collection system. The thick solid lines indicate permanent Ethernet connections.

Getting seismic data from a GSN station using Internet via a local computer is simple. The user uses the Telnet to login to the station. Once logged in, he can check available seismic data and use the FTP file transfer protocol to copy the data to the local computer. The process is easy to automate. Fig. 8.12 shows the communication links for the GSN network. It is seen that almost all stations have a permanent connection and consequently almost all continuous data is transmitted by the computer network to IRIS. Only going back to 2001, the majority of stations were dial up and data had to be sent to IRIS on tape.

temporary memory and the link's throughput will suffice in case of large, long-duration events.

### **8.6.7 Error-correction methods used with seismic signals**

All digital communications experience errors. In the transmission of seismograms this is particularly fatal since just one bit of error might result in a spike in the data with a value a million times larger than the true seismic signal. Obviously, this could wreak havoc in trigger systems, and one byte missing in an event file might corrupt the whole event file.

One of the principles of error correction is that data is sent in blocks, e.g., 1 s long, and along with the block of data there is some kind of 'check-sum'. If the check-sum does not tally with the received data, a request is sent to retransmit that particular block of data. Obviously this type of error correction requires duplex transmission lines and local data memory at the remote station. If only one-way transmission is available, the errors can not be corrected using the check-sum method but they can be detected and appropriate action taken at the receiving end. However, loss of data is inevitable. Error correction can be utilized at different hardware and software levels and can be of various types.

Proprietary error correction is used in many systems on the market. In these cases, the system operates over dedicated links and all the responsibility for transmission and error correction lies with the system. An example would be a digital radio link to remote stations that uses a manufacture's protocol for error correction. The protocol in this case would be built into the commercial product.

Standardized hardware error correction is another possibility. The hardware unit, where the data enters the digital link and where it comes out, has its own error correction built in. From the user's standpoint, it is assumed that no errors occur between the input and output of this hardware. The most common example of such hardware error correction is a telephone modem that uses internal, industry-standard error correction.

Computer networks use their own error-correction methods. When computers are linked with common computer network protocols like TCP/IP, error correction is built in from computer to computer. This is obviously the best solution, however it requires that the seismic remote stations operate quite sophisticated software. This is now the most common form of low level error correction.

Satellite data transmission links usually use forward error-correction (FEC) methods. FEC works on simplex links and doesn't require any retransmission of data blocks to correct errors. FEC is similar to check-sum error detection. By comparing the transmitted check-sum and that of the received data, corrections can be made. One drawback, however, is an increased data channel bandwidth due to a significant data overhead dedicated to error correction.

One should carefully consider the interplay between the error-correction system built into a seismic system with that of the particular communication equipment to be used.

### **8.6.8 Seismic data transmission and timing**

All digital data acquisition and transmission systems create a certain time delay or latency. This delay depends on the digitizer, the digital protocol used for transmission and the computer receiving the data. For this reason, nearly all digital field stations time stamp the data at the remote station and subsequent delays in the transmission have no effect on timing accuracy. However, there are also digital network designs where the timing takes place centrally. This can be done if the digital data arrives at the central site with a predictable or measurable time delay. The central computer must then time stamp the data when it arrives in real time and later correct it for the known transmission and digitizer delays. One advantage with this system is that only one clock is needed for timing the network. A further advantage is a simpler and less expensive remote station consisting only of a sensor and a digitizer. The disadvantage is that timing accuracy is not as good as with time stamping at the remote sites because time delays are known only with a limited precision and they may also vary in time. Also if the central clock or its synchronization with GPS time signals fails, the whole network fails. Most networks are moving towards time stamping at the station because GPS clock prices are now a small fraction of total digitizer costs.

### **8.6.9 Notes on dial-up phone lines and selection of modems**

Dial-up phone lines are sometimes proposed for seismic data transmission because they are readily available and apparently cheap. However, they have important limitations of which one must be aware. First, continuous seismic data transmission is not possible via dial-up lines. Second, their throughput is, in practice, frequently limited in spite of the high baud-rate capabilities of modern modems.

In practice, dial-up weak-motion networks based on phone lines can not 'digest' earthquake swarms and the numerous aftershocks after strong events. Therefore, they are an appropriate choice for low seismicity regions only. In addition, as they often do not function for several hours after strong events, due to either especially high usage of the public phone system or technical difficulties, they may not be the best choice for networks with the predominant purpose of giving seismic alarms. On the other hand, however, the USGS National Strong-Motion Program's dial-up network of about 200 stations (out of a total of 645 stations) ([http://nsmg.wr.usgs.gov/near\\_real\\_time.html](http://nsmg.wr.usgs.gov/near_real_time.html)) has successfully contributed to local ShakeMaps (<http://quake.usgs.gov/research/strongmotion/effects/shake/about.html>) in California since 1999. The data typically are downloaded, processed, and exported automatically to clients within 3-5 minutes after strong-ground shaking begins.

In many countries, public phone networks have specific properties and special 'tricks'. Therefore it is advisable to purchase modems locally. In general, it cannot be recommended to use modems for a new network.

## **8.7 Some network examples**

Along the lines described in the preceding section, some more examples are given of different types of seismic networks in operation, briefing both on their technical solutions and purpose.

### 8.7.1 International Monitoring System (IMS)

In recent years, a new global network, the International Monitoring System (IMS) has been set up aimed at monitoring the Comprehensive Nuclear-Test-Ban Treaty (CTBT) (see [www.ctbto.org](http://www.ctbto.org), Chapter 15 of this Manual, and Barrientos et al., 2001). The IMS is composed of seismic, infrasound, hydroacoustic and radionuclide stations. The seismic network consists of 50 stations designated as “primary”, mostly arrays (see Chapter 9), with real-time data transmission to the IDC of the CTBTO in Vienna, Austria. In addition there are 120 “auxiliary” stations that provide data on request to the IDC. Many of the auxiliary stations are members of the Federation of Digital Broadband Seismograph Networks (FDSN; see Fig. 8.4 and <http://www.fdsn.org>). The IMS network (Fig. 8.13) is currently the largest and most modern physical real-time network in the world. However, when requesting data from auxiliary stations, it works like a virtual network where the real-time network makes the detections and preliminary locations and then requests additional information from remaining stations for improving these preliminary findings.

**Fig. 8.13** Stations in the International Monitoring System (IMS).

### 8.7.2 Southern California Seismic Network (SCSN) (by E. Hauksson)

The authoritative earthquake-monitoring region of the Southern California Seismic Network (SCSN) extends across southern California, from the US-Mexico international border to Coalinga and Owens Valley in central California. The SCSN also reports on earthquakes in northern Baja California, Mexico, because these could possibly also cause damage in the United States. The region is home to almost 20 million inhabitants, including two of the ten

largest cities in the United States (Los Angeles and San Diego) and the two largest harbors (Los Angeles and Long Beach) in the Nation.

The SCSN operates about 300 seismic stations and receives real-time waveform data from an additional 125 stations operated by partner networks (Fig. 8.14). The SCSN seismic stations can be divided into three groups. First, the most modern group of 167 SCSN stations consist of broadband sensors, strong motion sensors, and high resolution dataloggers for digitization and data communications. The data from these stations are used for real-time determination of earthquake locations, magnitudes, moment tensors, and amplitudes for ShakeMap. The second group consists of about 35 stations that are equipped with only strong motion sensors and a datalogger. These stations provide amplitudes for ShakeMap and occasional arrival-time picks. The third group consists of 125 short-period stations that use legacy analog, frequency-modulated (FM) audible tone technology and Earthworm digitizers for data acquisition. Although, the amplitude data have limited dynamic range, these stations provide arrival-time picks for improved location and depth determination as well as coda duration for determining magnitudes of small earthquakes.

The data flow path from the remote seismic stations includes the on-site equipment, the data communications path, and a data acquisition computer at the central recording site. The last mile data communications to each site may use copper wire, spread-spectrum radios, or optical fiber. The main long-haul data communications include digital phone lines (frame relay or T1 lines) and digital microwave circuits. The waveform data are acquired by front-end processors that broadcast the data on a private local network. Many computers that are connected to this network, capture and process the waveforms or capture the data for archiving. For instance, a processing thread of Earthworm modules carries out the real-time picking of arrival-times, association, and hypocenter determination. A different thread harvests amplitudes and determines local magnitudes. Similarly, an earthquake-early-warning processing thread captures the waveform data to facilitate development of algorithms to estimate the size of the event quickly.

The Southern California Earthquake Data Center (SCEDC) archives and distributes all SCSN data and products. As the SCSN processes the data for detected earthquakes, outside researchers can also access all the data in the database, within minutes or as soon as the data are entered into the archive. The SCSN products include the southern California earthquake catalog, event gathers (triggers) of waveforms for nearly all events back to 1981 and for some events extending back to 1976, continuous broadband waveforms from 1999 to present, continuous short-period waveforms since 2008, and continuous strong motion waveforms since 2010. The SCSN and the SCEDC have maintained and published a catalog of earthquakes above magnitude 3.25 since 1932 and above magnitude 1.8 since 1980 with consistent magnitudes over the whole time (Hutton, *et al.* 2010). See also: <http://www.scsn.org>; <http://www.data.scec.org>.

A complementary information about the California Integrated Seismic Network (CISN) is contained in IS 8.4.

**Fig. 8.14** The Southern California Seismic Network (SCSN) in 2010. Both SCSN operated (shown with red and green symbols) and partner network stations (shown with blue symbols) recorded by the SCSN are shown. BB- broadband seismometer, SM- strong motion instrument.

### 8.7.3 Japanese seismic networks (Hi-net, F-net, and K-NET/KiK-net), operated by the NIED (by Shin Aoi)

Four seismic networks are presently operated by the National Research Institute for Earth Science and Disaster Prevention (NIED) in Japan (<http://www.bosai.go.jp/e/>) (Fig. 8.15).

**Fig. 8.15** Japanese Seismic Networks (Hi-net, F-net, and K-NET/KiK-net; status in 2010).

The first one is a high sensitivity seismograph network, named Hi-net, which comprises about 800 stations. At each Hi-net station a short-period, velocity-type seismograph is installed at the bottom of a borehole with a typical depth of 100 to 200 m (the deepest borehole reaches

3500 m depth). The second network is a broadband seismograph network, named F-net, which comprises about 70 stations. At each F-net station a broadband seismograph (STS-1 or 2) and a strong-motion sensor having a velocity-proportional response, are installed at the end of a horizontal tunnel of about 50 m length. Both Hi-net and F-net data are continuously transmitted to NIED via a TCP/IP network. The third network is a strong-motion seismograph network, named K-NET, which comprises more than 1000 stations. At each K-NET station an accelerometer is installed on the ground surface. The event-triggered data are automatically sent from each K-NET station immediately after the triggering. Another strong-motion seismograph network, named KiK-net, has its sensors installed in the same boreholes used by the Hi-net stations. Each KiK-net observation point is equipped with two accelerometers, one at the ground surface and one at the bottom of the borehole. Data collection procedure for the KiK-net is almost the same as that for the K-NET.

All data from these networks are freely available through the Internet. The Hi-net data are sent to the Japan Meteorological Agency (JMA) and used by the “Earthquake Early Warning” system, operated by JMA. Seismic intensities recorded by the K-NET, which is part of the nationwide seismic intensity network, are widely broadcast by television and radio stations. Many results, such as ground-motion prediction equations and underground structure models, have been obtained using a huge amount of data and related information from the above mentioned networks and largely contribute to a reliable seismic hazard evaluation. For more information, please see the webpages of the

- J-SHIS (Japan Seismic Hazard Information Station; <http://www.j-shis.bosai.go.jp/?lang=en>);
- NIED (<http://www.bosai.go.jp/e/>);
- Hi-net (High sensitivity seismograph network (<http://www.hinet.bosai.go.jp/>);
- F-net (Full range broadband seismograph network (<http://www.fnet.bosai.go.jp/top.php?LANG=en>);
- K-NET (Kyoshin strong-motion network (<http://www.k-net.bosai.go.jp/>);
- KiK-net (Kiban Kyoshin strong-motion network of vertical arrays (<http://www.kik.bosai.go.jp/>).

#### **8.7.4 China seismic networks** (by Liu Ruifeng and P. Bormann)

Since 2008 China has the following seismic networks (status as of December 2010):

- National Seismic Network with 145 stations, complemented by 2 small seismic arrays with 9 stations each;
- 31 Regional Seismic Networks with 792 stations in total;
- 6 local networks with 33 stations in total for volcano monitoring;
- 800 mobile seismic stations (600 for research projects, 200 for fast response deployments after strong earthquakes).

The National Seismic Network is an earthquake monitoring network with uniformly distributed seismic stations all over China. The average distance between seismic stations is about 250 km, except in the Qinghai-Tibet Plateau. Of the 145 stations of the National Seismic Network, 16 stations are equipped with Chinese made three-component very broadband seismographs of type JCZ-1, which have a flat velocity response from 360 s to 50 Hz and a flat acceleration response from 360 s to DC. At the other 129 stations, Chinese broadband seismometers of the type CTS-1 have been deployed, which have a flat velocity response from 120 s to 50 Hz. Detailed instrument parameters are given in the Data Sheet DS

5.1. The locations of these stations have been plotted in the top panel of Fig. 8.16 (top), with different symbols for these different types of instruments.

**Fig. 8.16 Top:** The China National Seismic Network and **Bottom:** the Chinese regional seismic networks.

Based on data from both national and regional seismic stations, CENC is capable of detecting  $M_L 2.5$  earthquakes in most areas on the Chinese mainland. In most of North China, northeastern China, central China, some parts of northwestern China and eastern coastal areas of China, events are detected down to  $M_L 2.0$  and in the key areas for earthquake surveillance and protection as well as in heavily populated major cities the detection threshold is as small as  $M_L 1.5$ . The combined use of GSN and CENC data greatly increased the speed of information release and location accuracy of earthquakes in China's border areas or outside of China.

CENC produces fast catalogues in several steps. A first fully automatic catalogue is available after 2 minutes, the primary catalogue (including interactive measurements) for Beijing region within 8 min, for other regions after 12 min, and the final catalog for Beijing in 10 min, for other regions in 20 min. Besides this, CENC compiles all catalog data, also of the regional network centers. These data are available for general use via <http://data.earthquake.cn> and further information is provided on <http://www.ceic.ac.cn>. The quick production of specialized complementary data such as fault mechanism and moment tensor solutions, reconstruction of rupture processes, the production of shake maps and so on lies in the responsibility of the Geophysical Institute of the CEA in Beijing, which also serves as a back-up center for CENC.

### 8.7.5 German Regional Seismic Network (GRSN) (by K. Stammer)

The German Regional Seismic Network (GRSN) currently consists of 27 stations and the Graefenberg array (GRF), consisting of 13 stations. They are the seismological broadband backbone of Germany. These stations have been operated continuously since 1976 (GRF), and 1991 (first stations of the GRSN), respectively. All stations are equipped with broadband sensors, in most cases with Streckeisen STS-2 sensors which have a flat, velocity-proportional response characteristic in the frequency range 8.33 mHz to 40 Hz. The GRF array was upgraded from STS-1 to STS-2 sensors in the year 2006. These GRF stations are operated by the Federal Institute for Geosciences and Natural Resources (BGR) whereas the GRSN sites are operated in collaboration of the universities in Germany, the Geoforschungszentrum Potsdam (GFZ) and the BGR.

The stations installed aim at monitoring and collecting high-quality data from regional and global seismic events as well as at recording and locating events with  $M_L > 2$  on German territory. All stations of GRF and GRSN are continuously recording, have a network connection via DSL or cell phone network and transmit their data in near-real-time to the Seismological Observatory of the BGR in Hanover using the SeedLink data protocol (except station GTTG which currently is using CD1 data protocol).

Since the local networks of the German states Saxonia and Thuringia also openly offer their continuous data via the Seismological Observatory of the BGR, these data are available there as well as those from the GRF and GRSN. These local networks operate currently 21 stations in total, mostly equipped with mid-period instruments Lennartz LE3D5s (flat response down to 0.2 Hz), only a few stations have broadband instruments like Streckeisen STS-2 or G ralp CMG 40T.

Fig. 8.17 shows the station sites of the Gr fenberg Array (GRF), the German Regional Seismic Network (GRSN) (yellow triangles) and of the associated local network stations (red

triangles). More details on the stations of GRF and GRSN are given on the websites <http://www.seismologie.bgr.de> and <http://www.szgrf.bgr.de>, which also provide information on available earthquake lists, bulletins, waveform data, station information, long-period and short-period dayplots of station recordings, the SHM analysis software manual as well as links to international and German seismic services and centers.

**Fig. 8.17** Map of the station sites of the Gräfenberg Array (GRF) and the German Regional Seismic Network (GRSN) (yellow triangles) and associated local network stations (red triangles). Figure from [http://www.szgrf.bgr.de/station\\_map.html](http://www.szgrf.bgr.de/station_map.html).

### 8.7.6 Norwegian National Seismic Network

The network is a typical internet based real-time network operated by a combination of different systems. The network consists of a total of about 50 stations (Fig. 8.19), where some of the stations belong to networks in other countries. The three stations on Jan Mayen are the last ones still connected in an analog sub-network.. Stations are equipped with either short-period or broadband seismometer, digitizer, recording computer and communications equipment, The majority of the data is continuously collected in the NNSN system from field stations with SeedLink. The acquisition at the field stations is done with the SEISLOG software (Utheim et al, 2001) where both triggers and continuous data are produced. The central network triggering is done with EarthWorm. Triggers from EarthWorm and SEISLOG are merged and moved to the final SEISAN data base using SEISNET. Likewise the continuous data is collected from all systems, homogenized and moved to SEISAN using SEISNET.

**Fig. 8.19** Norwegian National Seismic Network (NNSN) and associated stations. Red and blue NNSN stations are operated by the University of Bergen (UiB) and NORSAR respectively and yellow stations are contributions from other networks.

## 8.8 Seismic shelters

### 8.8.1 Purpose of seismic shelters and lightning protection

Civil engineering structures at seismic stations assure a good mechanical contact between seismic sensors and non-weathered, solid bedrock. They protect equipment from temperature, humidity, dust, dirt, lightning, and small animals. The shelter should also provide a good, low-resistance electric ground for sensitive electronic equipment and lightning protection, as well as easy and safe access for equipment maintenance and servicing. The well-engineered seismic shelter structure must also minimize distortion of seismic signals due to structure-soil interaction and man-made and wind generated seismic noise.

Seismic sensors require a stable thermal environment for operation, particularly BB and VBB sensors. With passive sensors, mass position may change too much and with active sensors, temperature changes result in an output voltage drift, which can not be resolved easily from low-frequency seismic signals. This can greatly reduce the signal-to-noise ratio at low frequencies or even clip the sensor completely. Also, many active sensors require mass centering if temperature slips below a few °C or the temporal temperature gradient is too large. Less than 0.5°C peak-to-peak temperature changes in a few days should be assured for good results when using broadband sensors. This is not a trivial requirement for a seismic shelter. Extremely demanding (usually non-vault type) VBB shelters can assure even better temperature stability. Peak-to-peak temperature changes as small as  $\sim 0.03^{\circ}\text{C}$  in two months (Uhrhammer et al., 1998) are reported for the very best shelters. Passive SP seismometers and accelerometers are much less demanding than BB and VBB seismometers with respect to the thermal stability of sensor environment. Many will work well in an environment with many degrees of temperature fluctuation.

Two vital, however often overlooked issues with potentially fatal consequences, if neglected, are lightning protection and grounding system. Lightning is the most frequent cause of seismic equipment failures. One needs to research the best lightning protection for each particular situation (lightning threat varies dramatically with station latitude, topography, and local climate) and then invest in its purchase, installation and maintenance. Several seismic networks have lost half or more of their equipment less than two years after installation because network operators simply neglected adequate lightning protection measures. A good, low-impedance grounding system keeps instrument noise low, allowing proper grounding and shielding of equipment and cables. It is a prerequisite for a good lightning protection system and is also absolutely required for an interference free VHF or UHF RF telemetry.

In some areas a light fence may be required around the vault to minimize man- and animal-made seismic noise and to protect stations against vandalism. The area covered by the fence may range from 5 x 5 m to 100 x 100 m, depending on several factors, e.g.: what kind of activity goes on around the site; the population density in the vicinity; the ground quality; natural seismic noise levels; and the depth of the vault. Note that fencing often represents a significant portion of the site preparation costs.

Inadequate site preparation and seismometer placement can easily wipe out all the benefits of expensive, high-sensitivity, high-dynamic range seismic equipment. For example, thermal and wind effects on a shallow seismic vault located on unconsolidated alluvial deposits instead of

bedrock can make broadband recording useless. It is pointless to invest money in expensive seismic equipment only to have its benefits wasted because of improper site conditions.

### **8.8.2 Types of seismic shelters**

The three main types of seismic shelters are:

- surface vaults which are the least expensive and by far the most frequently used, however they suffer the greatest level of natural and man-made seismic noise (see 7.4.2);
- deep vaults placed in abandoned tunnels, old mines or natural caves which are usually the best locations with respect to the price/seismic-noise-performance ratio, however, they may not be available and sometimes require extensive cabling, which can increase their cost (see 7.4.3);
- borehole seismic stations with depths from 10 to 2000 m are the best choice from the perspective of seismic noise. Improvement of the signal-to-noise ratio of up to 30 dB in ground velocity power density at about 0.01 Hz can be obtained by a 100-m deep hole. For high frequencies above 1 Hz the greatest gains in noise level reduction are realized within the first 100 m of hole depth. Wind-generated high frequency noise can be attenuated as well, however a complete shielding from it is possible only with a very deep borehole (Young et al. 1996). Boreholes are expensive. They may cost from US\$ 5,000 to US\$ 200,000 for the borehole itself, plus the cost of borehole type sensors, which are significantly more expensive than regular surface sensors. Boreholes are used principally in regions covered entirely by alluvial deposits where sites with good bedrock outcroppings are not available; or for the most demanding research work requiring low tilt-noise in horizontal component BB and VBB installations (see 7.4.5).

Shallow boreholes with a depth from a few meters to 15 m are sometimes used instead of surface vaults for pure economic reasons. A 15-m deep surface vault in a difficult terrain may cost more than a shallow borehole of the same depth. Seismic noise improvement in such shallow boreholes is negligible.

In terms of network cost, it might be cheaper to increase seismic station density to achieve a desired detection level rather than install a few borehole systems

### **8.8.3 Civil engineering works at vault seismic stations**

Today, seismic stations are most often in the ground vault form. The massive, solid concrete "seismic piers", traditionally found in old seismic observatories, are no longer built. Above-ground buildings or shelters are not desired at all. In fact, above-ground structures are far less suitable than underground vaults because of potential structure-soil interaction problems as well as wind generated seismic noise caused by the above-surface structural elements. (Bycroft, 1978; Luco et al., 1990). Also, sufficient thermal stability of the environment is much easier to achieve in an underground vault. If small buildings of any kind already exist at the selected location, make sure the seismometer vault is placed far enough away to minimize wind-generated noise as recommended already in the old Manual of Seismological

Observatory Practice (Willmore, 1979) (see IS 7.3). The structure of the vault should be light and above-ground parts kept to a minimum, creating as little wind resistance as possible.

Surface seismic vaults usually measure between 1 and 2 m in diameter, depending on their depth, the amount of installed equipment and the desired ease of maintenance. They are from 1 to 10 m deep, depending on the depth, quality, and weathering of bedrock at the site. Round or rectangular cross sections are equally suitable. Examples of their design are given in Figs. 7.39 and 7.40.

## **8.9 Establishing and running a new seismic network**

### **8.9.1 Planning and feasibility study**

#### **8.9.1.1 Goal setting**

The very first step toward establishing a new seismic network is understanding and setting the network's goals. These goals can differ significantly (see Tab. 8.1 in 8.3.5). The same applies to the seismic system requirements. Also, just as each country has unique seismicity, seismotectonics and geological formations, so every seismological project has unique contextual combinations that one must consider in order to find the optimal system design for that project.

Several issues must be addressed:

- the user's interests in ranked order: local seismology (epicentral distances < 150 km), regional seismology (epicentral distances between 150 and 2,000 km), and/or global seismology (epicentral distances > 2,000 km);
- the main purpose of setting up a network is usually either to monitor a region's general seismicity or to perform special studies (monitoring of special seismotectonic features, of important civil engineering structures, of engineering and/or nuclear explosions, of man-induced seismicity, etc.);
- the relative importance to the project's alarm function for civil defense purposes: Is the seismological research aimed at the long-term mitigation of the country's seismic risk or at the scientific research of the Earth's deep structure.

Many countries that have little or no seismic equipment should initially consider buying a system to monitor the region's general seismicity. They should expect the new system to help mitigate the region's seismic risk over a long period of time. Nevertheless, even for a project of such a well-defined scope, several questions must still be answered, including the country's needs as well as its financial, personnel, and infrastructure capabilities:

- how big is the region to be monitored?
- what is the seismicity level in the region?
- what is the institution's existing level of seismometry knowledge, and what are its resources for improving that knowledge?
- what is available in terms of communication infrastructure?

- how much money is available to establish the system?
- how many staff are available, per year, to operate and maintain the system, and to support research work using the system's data?

Having realistically quantified the above facts, one can then begin shopping for a seismic system that meets those criteria. There is always a trade-off between desires and reality. This procedure ensures that the new network will perform successfully in the existing environment, if carried out realistically.

If there are few or even no seismology experts available in the country, it is advisable to get help from consultants in the international academic world who are independent of commercial interests. In this early phase, focus on your country's specific socioeconomic needs and seismic awareness, and do not worry too much about specific equipment. Wait until the later phases of network design to contact sales and system engineers from seismic equipment manufacturers for help in defining the technical details of your system.

### **8.9.1.2 Financial reality**

Often, newcomers to seismology do not know how to allocate their finances to obtain the optimal seismic network design. Too often they spend the majority of their network funds purely on purchasing equipment, even though an identically important expenditure is required for proper operation of this complex equipment. To make sure one has correctly prepared for the purchase of seismic network equipment, one's budget must include money for the following:

- a feasibility study that examines potential network layouts, site selection, and potential seismic systems;
- preparation of remote stations;
- installation of the central-recording site;
- purchase of the network equipment;
- cost of installation, training, maintenance, and long-term support;
- cost of salaries and training for the new scientific and technical personnel usually required;
- network operation costs, including personnel, data transmission, data processing hardware and software, printing, backup storage, consumables, and spare parts;
- network servicing and maintenance cost.

The five figures on the following pages show examples of funding proportion among several different established seismic network projects. The numbers in the figures show the amounts allocated to different tasks (normalized per single station), both in thousands of US dollars and as a percentage of the project's total cost.

Fig. 8.20 shows an approximate cost distribution (per station) for establishing and operating the global seismic network (GSN) during five years, according to the IRIS plan 1990-1996. The IRIS consortium is composed of universities in the USA and other countries with a research program in seismology. Not only did this network use the most demanding and expensive equipment available, expensive site preparation and worldwide maintenance were often required which increased the cost per station.

**Fig. 8.20** Cost distribution of establishment and 5-year operation of a global seismic network (GSN) station. Number in ( ) is percentage of the project's total cost.

Fig. 8.21 shows details of the IRIS GSN system's establishment costs (excluding all operations costs; again, costs are averaged per station). Surface vault seismic stations are considered only. IRIS constructed many of the sites of GSN network as deep, expensive borehole installations. Even if they are not taken into account in this figure, IRIS still allocated substantial funds for the vaults and to tasks other than equipment buying.

**Fig. 8.21** Cost distribution of establishment of IRIS GSN surface vault seismic stations. In this and the following figures the number in ( ) is percentage of the project's total cost.

Fig. 8.22 shows a distribution of the finances which a developing country spent to establish a reasonably large seismic network, using analog RF telemetry. The country's significant investment in services (21.6%) paid for training at the factory and during installation, as well as one year of the manufacturer's full-time engineer support. These expenditures were critical for the successful start-up and operation of this network.

Fig. 8.23 shows a negative example of cost distribution, for a small, yet technologically demanding seismic network. Note the small amount invested in tasks other than equipment-purchases, particularly the site preparation works; 4.1% is surely not sufficient, making it difficult to believe that these sites could provide ample working conditions for such demanding sensors as very broadband (VBB) STS1 and STS2 seismometers. The relatively high amounts spent for services (9.3% for installation) came mostly because the purchasers desired a turnkey type of system. With no experiences in seismometry, the chances of efficiently using the installed equipment seem small.

**Fig. 8.22** Cost distribution of a relatively large national seismic network with 20 SP seismic stations, strong-motion instrumentation, and analog FM telemetry.

**Fig. 8.23** Cost distribution of a small, technologically high-end seismic network with an inappropriate allocation of funds.

Fig. 8.24 shows another example of a national seismic network installed in a large country and using high-end technology and duplex, digital telemetry system. But again, despite the network's size, the most modern equipment, and the central-recording equipment for two centers, the country only invested about 60 % of its total project funds in the equipment. The other half of the money was spent on follow-up services, including a great deal of training and two years of full-time engineer support provided by the equipment's manufacturer.

**Fig. 8.24** Cost distribution of a very large national, high-end technology, duplex-digital RF and phone-line telemetry seismic network with two central-recording centers.

The funding distributions shown in Figs. 8.20 through 24 are approximate and for illustration purpose only. Generally, the prices of seismic equipment are somewhat lower today. Actual conditions (including the type of network, the level of existing local technical knowledge, local labor prices, and the type of seismic site preparation required) will change from country to country, thus significantly influencing distribution of the funds. Regardless, the main message of these figures stays the same: one should not spend almost all the allocated funds on equipment. Despite deviations and the differences in absolute cost, these figures seem to indicate that the percentages of the total cost for each task remain nearly the same from network to network. As a rule, one should allocate at least one third of the money for a feasibility study, for establishing the proper working conditions, and for gaining the seismic expertise necessary to exploit the purchased equipment.

### **8.9.1.3 Basic system engineering parameters**

Once the goals are clear and the funds properly allocated, one has to clarify the entire project's interrelated seismological and technological aspects. Attention should be paid to:

- the size and the layout of the proposed seismic network (this should affect the choice of the type of transmission links for transmission of seismic data from the remote stations to the center);
- the seismicity level to be monitored - in other words, the amount of data one will deal with (this should affect data transmission equipment, central processing site's real-time and offline capabilities, whether the system will need continuous or triggered data recording capabilities, if and what type of trigger algorithm it will use, the type of data archive system; this should also affect the partitioning between weak-motion and strong-motion equipment);
- how accurate and where one wants the network's central-recording site to be located (this will affect the number of stations and the network's layout);
- the importance of the new system having alarm capabilities for civil defense purposes and the desired alarm response time (this should influence which data transmission links will be chosen, as well as how much real-time processing power will be needed at the central-recording site);
- the amount of technical reliability one expects from the system (this should affect the choice of data transmission links, how much hardware system redundancy one can afford for mission critical applications, like auto-duplicating disk drives, tandem computers, etc., as well as decision between 'office-grade' and industrial-grade computers);
- the desired robustness of the system in terms of functioning throughout damaging earthquakes (this should influence the selection of data transmission links, of power backup utilities for the remote stations and the central-recording site, and last but not least, of seismic vulnerability of the building that houses the central processing site).

After reasonably assessing these aspects and making a decision for each unique situation, one can then create a rough system design and begin selecting equipment that best matches these goals. Obviously, certain tradeoffs will need to be made.

#### **8.9.1.4 Determining the layout of a seismic network**

Determining a layout for one's seismic network requires two steps: 1) determining the total number of stations required and their approximate locations, and 2) determining the final station locations. Since the first stage closely relates to the goals of the network and available funds, the network operator should delineate how many stations he requires and can afford to set up, and where approximately they should be located. Since the second stage typically requires knowledge of seismometry, seismo-geology, data transmission technology (if applicable), and seismic equipment capabilities and limitations, the operator, if not having the experience, may want to consult with others having the experience.

#### **8.9.1.5 Number of stations in a seismic network**

The number of seismic stations should be based on the goals of the network, the size of the network, and, of course, on the available funding. For space reasons we will not go into details on the minimum number of stations that are technically required for a given seismological goal, but following there is a short overview.

For determination of an event location (based on phase readings), the theoretical minimum is four independent measurements, such as three P-arrival times and one S-arrival time. However, remember that such results, due to their uncertainty, usually have little value. For a more accurate determination of location, six stations acquiring good records of an event should provide scientifically credible evidence of an event's location, and ten to fifteen stations with good azimuthal coverage all around the source (see criteria outlined in Table 1 and 2 plus Figure 1 of IS 8.5) and acquiring good quality records of the event should provide an acceptable basis for more sophisticated studies of the earthquake's source properties. IS 7.4 describes a program which permits detectability and earthquake location accuracy modeling of smaller size national networks. Examples of theoretical network optimization with respect to event location and other parameter determinations are presented and critically discussed in IS 8.7.

Larger countries or regions will require a greater number of stations, unless, of course, their interest is only in the strongest earthquakes. Yet, for networks covering a large region, large epicentral distances often prevent the triggering of distant stations, or the earthquake signals get buried in the seismic noise. Thus the total information available for a given event, unless it is a strong one, typically comes from only a portion of the total network. How one can assess under such varying conditions, with respect to precision-located "ground truth" GT5 criteria (e.g., Bondár and McLaughlin, 2009), the quality of an operational authoritative location scheme applied in the real-time event information service of the European Mediterranean Seismological Center (EMSC) is described in IS 8.5. How ground truth reference events, suitable for network performance and location quality evaluation, can be identified and collected by way of own high precision network locations is described in IS 8.6. And Murphy et al. (2005) present an example of the calibration of stations of the International Monitoring System (IMS) aimed at improving seismic event location.

Note that seismic researchers do not care much about the total number of stations in a network; what counts is the number of stations in the network that adequately record a given event ('adequately record' means that they triggered data acquisition, the records are not saturated and that the records have a high signal-to-noise ratio). Moreover, waveform analysis of digital, high dynamic range, three-component records leads to good results already with fewer stations. In principle, even a single well calibrated 3-component station can determine, via multi-phase phase identification and polarization analysis, the epicenter, source depth (if below the crust), origin time and magnitude of earthquakes with reasonable accuracy using global 1-D models and correcting for systematic biases (if any), that may depend on azimuth and distance or source region (see Chapter 11, section 11.2.6.2. and EX 11.2). For more details on location procedures and related problems, both for networks and single stations, see IS 11.1.

#### 8.9.1.6 Layout of a new seismic network

Although the spatial distribution of the stations in a seismic network is very important for the network's capabilities of event determination, due to limited space we will only give a few, brief recommendations. For seismic arrays and their special location procedures and performance see Chapter 9.

On a map, subdivide the region to be monitored into a series of reasonably irregular triangles having approximately equal areas. Avoid very narrow, long triangles. Avoid thinking in rigid patterns, such as locating the stations into perfect triangles, circles or straight lines, because such rigidity may result in "blind spots" - that is regions with poor event location determination. The corners of these triangles are the approximate points where one will try to locate seismic stations. Take into account any existing seismic stations in neighboring countries or regions as well. If there are none, push some of the seismic stations as close as possible to the borders of the region being monitored.

The geometry of the network will determine the accuracy of location in different directions, and a reasonably regular grid will give most uniform location accuracy. The worst configuration is a network with stations that are aligned (see Fig. 8.25 as an example).

**Fig. 8.25** Network geometry of aligned stations. The figure to the left shows three stations (S1, S2 and S3) almost aligned in the x-direction (left - right). The event has been located by using the distances to the three stations, and the shaded area in the middle gives an indication of the area within which the epicenter can be found. The figure to the right shows the same situation except that an azimuth determination has been made with three-component records at station S1. This limits the y-direction within which the epicenter can be located and thus reduces the epicenter error.

It is advisable to have realistic expectations concerning the earthquake depth determination based on phase readings. Previous studies (e.g., Francis et al., 1978; Uhrhammer, 1980; and McLaren and Frohlich, 1985) have shown that the accuracy of focal depths for shocks occurring in the vicinity of a seismic network is primarily a function of the geometry of the network, the number of the P- and S-phase arrivals read, and the adequacy of the assumed velocity model. Depths are generally more accurate for earthquakes where the distance from the epicenter to the closest station is less than the calculated focal depth for events located within the network or on its periphery. The accuracy of focal depths usually increases as the number of picked S-phase arrivals increases; however, systematic S-phase timing errors (due to mistaken identification of a converted phase as S) or "bad" S picks can degrade the focal depth estimation accuracy by several kilometers even when the azimuthal coverage is good (Gomberg et al., 1990). Estimate the depth of the shallowest events for which good depth control is desired then make sure that the average distance between stations in the seismic network does not exceed twice that depth. The latter is admittedly a tough requirement, especially in the large regions and in the regions where the events are typically shallow! Only a few small countries and practically none of the larger countries can afford such a dense network.

Yet, one can still temporarily afford to make the network denser in places. Buy a few portable seismic stations and then temporarily install them in any sub region of particular interest at the time. For example, such temporary networks are regularly established to perform aftershock studies in the epicentral region immediately after a strong event. At least for a time, this will drastically increase the seismic network's density in the region of interest, allowing the determination of much better locations, depths, and focal mechanisms. Such studies can be done with low-cost portable instruments since the main purpose is to get more phase readings.

Have realistic expectations also about the system's earthquake epicenter determinations. For events outside the seismic network, expect large errors in determining epicenters. Generally, do not expect reliable determination of events, unless the "seismic gap" (the largest of all angles among the lines connecting a potential epicenter with all the stations in the network that recorded the event) is less than 180 degrees. Thus, to increase the accuracy of epicenter determinations, especially for the events outside the seismic network, one needs to include data in the analysis from seismic stations in neighboring countries, as well as from any other available national or international sources. It is common practice to share near real-time data across the borders and integrate the data into a virtual seismic network. Acquiring this wider database is usually necessary for determining reliable event locations on the border or outside any seismic network.

### **8.9.2 Site selection**

The matter of seismic site selection is too often not given sufficient depth of study and attention in spite of the fact that a weak-motion seismic network can only have a high detection threshold if the sites have satisfactory noise levels, no matter how technologically advanced and expensive equipment is. If seismic noise at the sites is high, all or a part of the benefits of modern equipment with large dynamic range are lost. If an excessive burst or spike-type, man-made seismic noise is present, high trigger thresholds and therefore poor event detectability will result. If stations are situated on soft ground, the VBB or even the BB

recording can be useless and SP signals may be unrepresentative due to local ground effects. If the network layout is inappropriate, some event locations may be inaccurate or even impossible. For good results, many factors at the sites must be taken into consideration. A professional site selection procedure is therefore essential for success of any seismic network. There can also be specific reasons (e.g., political) why a station may have to be deployed in a particular place, but also then it may be possible to select the “better” site.

Generally, it is best to begin the process of site selection by choosing two to three times as many potential sites as one actually plans to use. Then each site is studied to see which sites meet as many of the criteria as possible. Gradually, one will eliminate the poorest sites and get down to the number of sites required plus two or three. By comparing the results of computer modeling of a few of the most likely network layouts (see IS 7.4) one will be able to make an informed decision about the best network.

Note that one should not rely too much on algorithms designed to optimize seismic network configuration (e.g., Kijko, 1977; Rabinovitz and Steinberg, 1990). This is because the theoretical optimum configuration can hardly ever be realized nor their predicted theoretical potential information gain be exploited under real conditions. Stations often can not be installed at the recommended locations due to factors such as inaccessibility, poor ground conditions, proximity of strong noise sources, lack of required power, or unavailable communication link.

On the other hand, these programs may be of help selecting the best of a few realistic network configurations (e.g., Trnkoczy and Živčić, 1992; Hardt and Scherbaum, 1994; Steinberg et al., 1995; Bartal et al., 2000). For an existing network, they could help decide how best to improve the network by adding new stations or which stations, if removed, would cause least harm to the network. Keep in mind, however, that the best configuration for locating earthquakes may not be optimal for source mechanism determinations, tomographic studies or other tasks (Hardt and Scherbaum, 1994). These various aspects of network optimization and performance assessment are richly illustrated and commented in more detail in a PPT tutorial, annexed as IS 8.7.

Here we will present only the basic steps of the site selection procedure. More details on this issue can be found in Chapter 7, sections 7.1 and 7.2.

The site selection procedure encompasses office and field studies. Off-site, “office” studies are relatively inexpensive and therefore the first ones to be performed. From an office, one can study maps and contact local authorities to gather information about potential sites. The first step is defining the geographical region of interest. The next step is to gather and examine existing geological faults, seismotectonic features, and all available information about seismicity in the area. If the main goal of the new network is monitoring general seismicity in an entire country, this stage is, of course, simpler. Then prepare a simplified map of regional seismo-geologic conditions showing the quality of bedrock. The rule is: the higher the acoustic impedance (acoustic impedance is the product of the density and the velocity) of the bedrock, the less the seismic noise and the higher the maximum possible gain of a seismic station. Next, study the topographical aspects of the possible locations. Moderately changing topography is desired. To study man-made and natural seismic noise sources in the region, one should evaluate road traffic, railway traffic, heavy industry, mining and quarry activities, agricultural development of the region, and any other sources of man-made seismic noise around the potential sites, along with the natural sources like oceans and lakes, rivers,

waterfalls, animals, etc. (see IS 7.3). Much of the information we need can be found on maps, geographic information systems or obtained by asking questions of local authorities.

Real-time communication is a requirement in most modern seismic networks and will add some constraints to site selection. Communication is typically based on Internet technology for radio, satellite, mobile phone and fixed line links. Radio and satellite links are the most flexible as they can be deployed almost anywhere. Mobile phone services and coverage vary strongly, but may be an attractive option. Fixed lines such as ADSL are generally inexpensive and provide high data rates, but are not available anywhere. If the new network is a radio frequency (RF) telemetry system, one has to correlate RF data transmission requirements with seismological requirements. Topographic profiling of RF paths based on topographical maps is performed. The next section "VHF, UHF and SS radio-link data transmission study" explains why this is highly recommended.

If one plans to use main power, the availability of main power lines and the distances to which new lines would have to be laid must be checked. The alternative is batteries, preferably charged by solar panels. It is also very important to research land ownership, animal habitats, land protection and future land use plans for the potential sites. It makes no sense to undertake extensive studies if one will be unable to use certain sites because of property ownership issues, endangered or protected animal species issues, or if it appears that future development will make the site unsuitable for seismic stations.

The climate at the sites also influences site selection and preparation. Temperatures, wind, precipitation, insulation data (for solar-panel powered stations), lightning threat, etc. may all influence site selection.

Field studies are the next step in the site selection process. Expect to make several visits to each site. A seismologist familiar with seismic noise measurements, a seismo-geologist, and a communications expert (if we are considering a telemetry network) should all visit each site. They should verify the ease of access to the site, search for local man-made seismic noise sources, which may not be apparent from maps, perform seismic noise measurements (of at least a few days duration), study the local seismo-geological conditions at the site, investigate the local RF data transmission conditions (if applicable), and on site verify power and phone line availability.

Local geology should be studied to determine its complexity and variations as well as seismic coupling between local seismic noise sources and the potential station site. To the extent possible, uniform local geology is preferred for seismic stations. The degree of weathering that local rocks have undergone is another important parameter, although it can give an unreliable estimate of the required depth of the seismic vault. The ideal approach for high-quality site selection is to make a shallow profile at each potential site to make sure the vault will reach hard bedrock. If this is too costly, then expect surprises when you begin digging seismic vaults. Many times it is a matter of almost pure chance what one might run into. Note that in some areas it will not be possible to reach bedrock.

After all these studies one ends up with two or three potential sets of the best suitable seismic stations. The resulting network layouts are then studied for the best network performance possibly by computer modeling. By comparing the results, one will be able to make an informed decision about the final seismic network layout.

### **8.9.3 VHF, UHF and SS radio-link data transmission study**

#### **8.9.3.1 The need for a professional RF network design**

The most frequent technical problems with radio-frequency (RF) telemetry seismic networks originate with inadequately designed data transmission links. Therefore we are discussing this topic separately. For more detailed description see 7.3.

The design of RF telemetry links in a seismic network is a specialized technical matter, therefore guessing and "common sense" approaches usually cause problems or even complete project failure. There are quite a few common misunderstandings and oversimplifications. The amount of data that must be transmitted and the degree of reliability required for successful transmission of seismological data are frequently underestimated. The significance of "open line of sight" between transmitters and receivers as a required and sufficient condition for reliable RF links is misunderstood. Frequently, over-simplified methods of link verification are practiced. However, the real issues in the RF link design and link reliability calculations are: the frequency of operation, Fresnel ellipsoid obstructions by topographic obstacles, the curvature of the Earth, the gradient of air reflectivity in the region, expected fading, potential-wave diffraction and/or reflections, time dispersions of the RF carrier with digital links, degradation of signal strength due to weather effects, etc. All these are specialized technical issues.

To prevent failures, a professional RF survey in planning a new seismic network is strongly recommended. It includes the calculation of RF links based on topographical data and occasional field measurements. A layout design based on a professional RF survey can significantly increase robustness of the radio network. The survey will:

- determine the minimum number of required links and RF repeaters in the network. Note that, in most designs, every RF repeater obviously increases the probability of link-down time and the price of the system;
- determine the minimum number of licensed frequencies required;
- determine the optimal distribution of RF frequencies over the network, which minimizes the probability of RF interference problems;
- chose in a less polluted RF space in the country;
- determine the minimum antennae sizes and mast heights, resulting in potential savings on antenna and antenna-mast cost.

The cost of a professional RF survey represents generally a few percent of the total investment. We believe that the combined benefits of an RF survey are well worth the investment, and are a major step toward the reliable operation of the seismic network.

### **8.9.3.2 Problems with RF interference**

Radio frequency interference caused by other users of VHF or UHF RF space in many countries is quite a common and difficult problem. There are several reasons for that. In some countries, there is confusion and a lack of discipline in matters of RF space: army, police, security authorities, and civil authorities may all operate under different (or no) rules and cause unforeseen interference. In other countries, poor maintenance of high-power communication equipment results in strong, stray radiation from the side lobes of powerful transmitters. This radiation can interfere with seismological radio links. Extensive, unauthorized use of walkie-talkies can also be the cause of problems.

The best, and more or less the only solution is to work closely with local RF experts during the design phase of a seismic network. They are practically the only source of information about true RF space conditions in a country. Note that RF interference problems are generally beyond control of seismic system manufacturers and seismological community. All RF equipment, no matter who manufactures it, are designed to be used in an RF space where everybody strictly obeys the rules. One also has to, as much as possible, avoid other high-power RF space users (see IS 7.2).

### **8.9.3.3 Organization of RF data transmission network design**

An RF layout design is always an integral part of a seismic site selection procedure. Theoretically the seismic system purchaser can perform it if he has adequate knowledge in this field. However, practice shows that this is rarely the case. Even if the RF survey is purchased from an independent company or from a seismic equipment manufacturer as a part of the services, the process still requires involvement of the seismic system buyer. For efficient office and fieldwork, the customer has to prepare beforehand an approximate initial seismic network layout, road and topographic maps, and climatic data. He has to make available knowledgeable staff members and well-informed local people acquainted with local conditions at the sites, who will join the site selection and RF survey field team. He should also assure efficient logistics during the fieldwork.

A detailed list of what to prepare is given in the IS 7.1.

### **8.9.4 Purchasing a seismic system**

There are different ways of buying equipment for a completely new network. If the user has little experience, it might be desirable to get all equipment and installation from one company while if the user has sufficient knowledge or can get help from other institutions, only equipment should be bought and possibly from several different companies in order to get the best price/performance. Buying all from one company is often a more expensive solution. However, compatibility between the different components is essential, but more difficult to achieve when mixing. Some countries/institutions require that equipment (and installation) go through a bidding process. The bidding process may help to carry out a more systematic evaluation and pay off. Some institutions insist that all equipment and services are obtained from a local representative. While there may be good reasons for this, it can increase the cost.

A very important requirement for the new network is specification of how and in which format the data is delivered. Today, most equipment is able to produce data in one of the standard formats used for processing, however the data must also be easily available for integration into one or several of the standard systems used for processing. Just recording all data continuously is not much help if there is no user-friendly software available to access and extract any part of that data. So an integral part of the specification is a requirement that the data must be delivered ready for processing in a given processing system.

#### **8.9.4.1 The bidding process**

While sending out a Request for Proposal and asking for bids on a new seismic system may be a good way to get started, there are a number of important issues one must be aware of when requesting bids or proposals. First, certain technical requirements and business standards must be met in order to be able to compare "apples to apples" when it is time to analyze the system proposals received. Second, in order to find the most suitable system, one needs to invest a fair amount of additional time in research and investigation before sending out the bid specifications. Namely, some very important issues may be hard to define in the Request for Proposal. The proposals can easily give unclear information regarding the following crucial issues:

- reliability of the equipment;
- user friendliness of the system;
- availability of long-term support by the manufacturer including true availability of spare parts in the next years;
- financial stability of the manufacturer.

In the Request for Proposal one should include all relevant basic technical information, so that the manufacturer can put together the corresponding technical solution. However, we recommend that the Request for Proposal does not contain an over-detailed technical description of the desired system. With too many technical details, one can end up limiting one's choices and even disqualifying the most suitable system just because a relatively unimportant technical detail can not be fulfilled.

Avoid buying brand new systems in the market unless you are really assured of excellent support from the manufacturer. Brand new systems frequently have more problems than older more tested systems. Their use will require a high level of knowledge and a really good working relationship with the manufacturer while solving these problems.

Some countries are required by law to accept the lowest bid. Unfortunately, crucial qualities like services, equipment reliability, user friendliness of the system, amount of factory testing, setup and long-term support might be easily lost if one bases the choice solely on the lowest price for all of the stated (but practically never really sufficient) requirements of the bid.

Manufacturers of seismic equipment can offer a turnkey system whereby they will purchase all of the necessary components not made by them. They will include their administrative labor costs for acquiring these components. Do not assume that they will be able to purchase every item at prices lower than you will be able to. Federal, state, and local governments and universities (typical operators of seismic networks) often have secured special pricing from vendors that can be substantially cheaper than what seismic equipment manufacturers can obtain.

#### **8.9.4.2 Selecting a vendor**

When evaluating the proposals, one should assess not only the technical qualities of the system, but also the quality of every manufacturer. It is a common practice that companies invite potential buyers to a promotion visit. This does not necessarily give relevant information on how well the system would perform. If a visit is desired, carefully select the people who will participate in these visits. In addition to a member fully responsible in financial issues, one member of the team should be the individual responsible for future operation of the network. Other members of the team should be those most knowledgeable and experienced in seismology, no matter what their position in the hierarchy or which institution they belong to.

Ask for visits with manufacturer's sales or system engineers. Data sheets themselves seldom give enough technical information about a seismic system. Sales and system engineers can provide all the details of a particular technical solution. Such visits, however, are less appropriate during the early stage of the project when one's goals are not yet specifically set. It is understandable that sales representatives will be biased toward the equipment of the manufacturer they represent. Visiting other networks of similar size in different countries is often better spent money than visiting a company trying to promote their equipment and may give more realistic information of reliability and capabilities of different equipment. Reliability and company service are important. This information will mostly be unavailable from the company offers and only by talking to other users can one find out. It is in itself no guarantee that the company is large and well known, although such a company might provide good long term service.

#### **8.9.4.3 Equipment selection**

As already mentioned, data sheets of seismic equipment alone seldom provide enough information. In addition, it is not easy to compare the data sheets of various manufacturers because each one, to some extent, uses a different system of specifications, measurement units, and definitions of technical parameters. In most cases small differences in specifications have no importance in real life, like e.g. if a digitizer has 22 or 23 bit resolution. The seismic equipment has a hardware and software component, which are almost equally important. The acquisition unit (digitizer possibly integrated) usually has a user interface that allows to change settings and monitor operation, but also to monitor and control the seismometer. The software also provides the functionality for real-time data transmission. When selecting a system it is important to evaluate the overall integration and not just to look at the performance of individual components. So for example, the digitizer with the best dynamic range is of no use in a real-time network if it does not have all functionality for data transmission.

Ideally, we recommend buying one piece of key equipment such as a sensor, a data logger, processing software with demo data or an RF link and testing the product yourself. In the case of large projects with adequate financing, manufacturers will often loan equipment for testing purposes free of charge. While it is ideal to get some firsthand experience before settling on which new system to purchase, this approach requires personnel who are knowledgeable about seismology and instrumentation.

The technical systems must be able to operate in the intended environment. Today most equipment is installed in protected locations like houses and vaults and communication is delivered by third parties (like a phone line), so in many cases there is no strict requirement for temperature and humidity. So paying extra money for a recorder which is able to sustain 2 m of water is wasted money if the unit is installed in a protected environment. Outdoor equipment today is GPS antennas which by default can be expected to be made for outdoor use and communication equipment. For the latter, usually only antennas are installed outdoors. The main indoor problem might be temperature and humidity.

Each technical system, or element in it, properly operates within a certain set of parameters, or "range". One should be familiar with these ranges and know where, within this range, the system will actually operate. If one or more of elements of the system are to operate at the extreme end of their operation range on a regular basis, most probably a different element or system should be selected. Note that there is always a price to pay for operating equipment under extremes. It is always best to have a safety margin in your system and do not expect it to operate continuously, efficiently, and reliably in extreme ranges.

#### **8.9.4.4 The seismic equipment market is small**

The global market for seismic systems and equipment is naturally quite limited. With very few exceptions, instruments are produced in small numbers. Inevitably, this sets a limit to the quantity and thoroughness of testing of the newly developed equipment. This is not a result of a lack of quality or commitment on the part of manufacturers in this field, but a simple, economic reality. Compared to industries with a far broader and more powerful economic base, like computer and electronic companies, seismic equipment moves into the field with relatively little testing, even by the most reputable manufacturers. In general, the equipment arrives with a higher than average number of bugs and technical imperfections that will need to be solved by the manufacturer and the user working in tandem.

Currently, most seismic equipment and technical documentation is less user-friendly and complete than desired. Customers are rarely given comprehensive and easy-to-follow instructions on how to setup and use the system. Equipment and software does not always arrive with the promised features. It may be possible to address some of these issues during acceptance tests.

#### **8.9.4.5 Processing software**

The majority of seismic network manufactures have relatively little experience in seismic signal processing and as a general rule, do not have adequate software. It simply does not pay to develop this kind of software. On the other hand, there are public domain software packages available, which can solve these tasks and these are often offered by the manufactures. However, very little training is offered and a new network operator may end up with an expensive network but very primitive processing tools. Therefore, obtaining adequate processing software and training is an important and integral part of the planning of a new network. Unfortunately this is often not the case and the value of the network can be greatly reduced.

## **8.9.5 System installation**

### **8.9.5.1 Four ways of seismic system installation**

Generally we can define four methods for the installation of a new seismic system.

- 1) The user installs the new system. Only ‘boxes’ are purchased. In this option, the customer is responsible for the proper functioning of the system as a whole and the manufacturer remains responsible for proper functioning of the elements, unless they are improperly used or installed. This approach gives the user great flexibility, but also the main responsibility. It is only an option if qualified staff can be appointed to this task and/or if local or international organizations can participate.
- 2) The manufacturer demonstrates installation on a subsystem (a few stations, a sub-network). The user installs the rest. In this case, the manufacturer and the user, share responsibility for the system functioning. This approach is often successful. However, the customer must have a certain amount of experience with seismic, computer, and communication equipment for this method to work.
- 3) The manufacturer installs the whole system with a full assistance from local technical and seismological staff that will be responsible for running, maintaining, and servicing the network in the future. Responsibility for making sure the system functions lies with the manufacturer. The main benefit of this approach for the users is that they learn an enormous amount during the hands-on installation and associated problem solving time. This is probably the most efficient method of training. The user should not expect savings and potential shortening of the installation time but rather some additional time and effort will be required from manufacturer. In our experience, this is the best way of installing a seismic network in a country where little or no experience with seismic equipment exists.
- 4) The manufacturer has the complete responsibility for installing a turnkey system and making sure it functions adequately without any assistance from the customer. In this case, the network will no doubt be successfully installed, but local staff members will not learn about its operation nor how to solve potential future problems. In general, this is not a desirable solution.

Two technical details relating to system installation should also be mentioned here. In the case that the system buyer will install the system or its parts, do not select the 'standard length' cables sometimes offered by seismic system manufacturers. The 'standard' cables rarely work well in the field. They are, according to Murphy's laws, always too short or too long. Do not loop or coil extra cable length because that will increase the threat of lightning damage, unnecessarily increase system noise, and in the end, you will be paying for the “extra” cable. Rather, ask for bulk cables with separate connectors or cables of a reasonable length margin and one-side mounted connectors only. During installation in the field they can then be cut to precisely the desired length. Note, however, that reliable, high quality soldering of connectors requires experience. Inexperienced technicians have little chance of performing the job correctly and poorly installed connectors are among the most frequent causes of problems at a seismic station.

### **8.9.5.2 Organization of civil engineering works**

Whatever construction work is needed to prepare the sites, it is usually arranged and paid for by the customer of the new network rather than the manufacturer of the seismic equipment. Very large national projects may be an exception to this rule. Site construction will require a great deal of preparation and involvement by the system buyer. There are generally a number of good design alternatives from which to choose and we suggest hiring a local civil engineering contractor to design the best solution for a particular system and specific circumstances in the country. A seismo-geologist and a civil engineer should supervise the construction work. Their main responsibility is assuring that the enclosure is watertight and that the sensors have a good contact with solid bedrock. The system's manufacturer can usually provide sketches and suggestions for the procedure and may also supervise the work, but usually does not provide true structural engineering drawings for seismic shelters. Working in tandem with a local civil engineer is usually a better choice because the engineer will be familiar with all local circumstances that are unknown to the manufacturer of the seismic equipment. Local builders know best what materials and construction methods are available and workable in a particular country. Do not "over-engineer" the project; it is usually not necessary to have a big civil engineering firm design every detail, oversee all seismic site preparation, and then build the site.

### **8.9.5.3 Summary of recommendations for setting up a new network**

- To ensure long term maintenance and get lowest possible operational cost, the user should build as much as possible of the network himself
- Study and visit other networks to learn the requirements
- Decide on communication
- Decide on type of network based on communication possibilities
- Decide on integration of all components into one system
- Make sure processing and data storage systems are in place (including training) before network installation is finished

#### ***Real time network***

- If a real time network there are two possibilities to ensure real time completeness of data(retransmission):
  - (a) Use public domain SeedLink with standard computers and digitizers. Several digitizers can be used. Requires some computer skills but is the cheapest and most flexible option.
  - (b) Use a company system where digitizer, communication protocol and receiving software is a company standard. Only equipment from that company can then be used. Simple and reliable but more expensive and less flexible than a public domain system.
- Triggering: All real time system should have a trigger. It is recommended to use one of the public domain systems such as EarthWorm and Seiscomp.

#### ***Networks with no communication***

This type of networks are mostly temporary but could also be permanent

- Chose a recorder with a standard interface and data recording format. Chose between
  - (a) A black box with built in software and a simple way to tap out continuous data

(e.g. memory stick). Usually a reliable solution and it often represent a robust mechanical solution

(b) A PC with a digitizer and a public domain software. Requires more computer skills, protected housing but can be cheaper and more flexible.

- Make sure software is available for handling and integration of the continuous data into the processing software data base.

## **8.9.6 Running a seismic network**

### **8.9.6.1 Tuning of seismic networks**

Before a seismic network can function with its full capacity, it must be tuned to local seismo-geological and system conditions. Tuning is especially important for networks that run in triggered mode. Unfortunately, many operators are not aware of the importance of fine-tuning.

The local and regional Earth's structure, the seismic network dimensions and layout, regional seismicity, seismic noise levels at station sites, seismic signal attenuation in the region, all play a role in these adjustments. One will not be able to correctly tune the system's recording and processing parameters until one has acquired sufficient experience with natural and man-made seismic noise and earthquake signals at all the sites in the network and until one fully understands the parameters that have to be tuned. Therefore, tuning a network takes normally months of systematic work. Because of the long time required to accomplish this task, the system's manufacturer simply can not do it. Only the network operator can correctly tune the network. Moreover, since seismic noise conditions at the sites may change with time, new stations may be added, the goals of the network may change, etc., re-tuning of the network will probably be required from time to time. In reality, tuning a seismic network is an ongoing task, which can not be done 'once and for all.'

Actual tuning procedures are manifold. Besides appropriate gain setting and accurate quantification at individual stations, the most important tuning is that of the trigger parameters:

- trigger threshold values;
- detrigger threshold values;
- trigger time windows' duration and other parameters;
- weights of individual stations in coincident trigger algorithm;
- grouping of stations into sub-regions for a coincidence-trigger algorithm;

Detailed discussion of individual parameters is beyond the scope of this text. Note that not all enumerated parameters exist in every seismic network and that some adjustments may be missing from this list. A thorough description and parameter adjustment procedure for the short-time-average/long-time-average (STA/LTA) seismic trigger algorithm is given in the annexed IS 8.1 on "Understanding and parameter setting of STA/LTA trigger algorithms". Further guidelines for other network tuning procedures may be added later as complementary Information Sheets.

The following are some of the offline seismic analysis software issues that must be studied and prepared for efficient routine observatory work, and parameters that have to be adjusted for correct analysis of seismic records:

- files containing information about data acquisition parameters (data acquisition configuration file(s));
- files containing data about geometrical configuration of seismic stations (network configuration file(s));
- parameter files containing sensor calibration data;
- Earth model parameters of event location program(s) (layer thickness, seismic-wave velocity, seismic station weights, epicentral distance weighing function, and similar parameters depending on the program used);
- automatic phase-picker parameters;
- magnitude scale parameters;
- preparation of different macros and forms for routine, everyday analysis of seismic signals.

Some parameters, e.g., for the Earth model, are often insufficiently known at the time of network installation and require long-term seismological research work, which results in gradual refinement of the model and increasingly better event locations.

No manufacturer can optimally pre-adjust all these parameters to the specific local conditions. Seismic networks usually come with a set of default values for all these parameters (factory pre-selected values based on 'world averages'). These values may work sufficiently well for the beginning of network operations, however, optimum seismic network performances requires reconsidering most of them.

#### **8.9.6.2 Organizing routine operation tasks**

Keeping one's network failure-free and in perfect working order while waiting to record earthquakes year after year requires hard and responsible work and a lot of discipline. Well-defined personal responsibility with respect to altering network operation parameters and strict obedience to the established procedures is an absolute must.

This goal is generally not simple to achieve. Seismic observatory staff will have to operate in a highly professional and reliable manner with:

- clearly defined personal responsibility for each task associated with the routine operation of the network and for other everyday analysis and archiving activities;
- regular maintenance of hardware and software;
- continuous verification of all tasks and hardware operations;
- maintenance of precise records of all relevant activities that effect data parameters, availability, continuity, and quality, such as changes to network operational parameters, processing procedures, data archiving, equipment maintenance and repair.

Regular processing of seismic data requires that all details of how data is processed and stored is well planned and that personnel are adequately trained.

Network recording parameters should be changed only if there is an important and well thought through reason. Because any change to the recording parameters will affect the network's ability to detect earthquakes, these changes should be avoided as much as possible. From the point of view of monitoring seismicity, ideally, there should be no changes for years after the network is fully adjusted. Nevertheless, those changes that are inevitably required from time to time should be kept to a minimum and carefully documented and archived.

Careful and continuous documentation of network operation parameters in a logbook, log file, or in the seismic database itself, is essential. This operational information should contain all information about data acquisition parameters and their changes, a documentation of all station calibrations, a precise record of each station's downtime, descriptions of technical problems and solutions, and descriptions of maintenance and service work. The exact times of parameter changes must be thoroughly recorded. This time-dependent information must become an integral part of the seismic data archive because without it the data can not be properly interpreted.

Usually a seismic network team is divided into a seismological and a technical group. This is fine as it relates to every day network operation activities and responsibilities. However, as much as possible, the basic technical as well as basic seismological knowledge should be 'evenly' distributed among the members of both groups. This favorably influences the general quality of the work of a seismic observatory. It also helps very much in many of critical situations, such as following a severe, unexpected technical problem, following a large earthquake, during the rapid deployment of portable stations following a main shock, or when any other situation dramatically increases the amount of work for a limited period of time.

The technical group must accept that no matter how modern and sophisticated the seismic network is that they operate; their customers are the seismologists. Therefore the seismologists must define the goals of seismic network operation and its working parameters. Frequently personal frictions may appear if this issue is not clearly defined by the management.

Many seismological observatories in high seismic risk regions must have people on duty at the central-recording site 24 hours per day. This may be a more or less explicit government requirement in order to be able to quickly notify public and civil defense authorities in the case of a strong, potentially damaging earthquake. No matter how understandable such desire may be, however, this working regime is really feasible only in a very large seismological institution. Only they have enough seismologists capable of quickly and competently interpreting seismic data. Even a fully-automated central recording and processing facility requires verification and confirmation of automatically determined earthquake parameters by trained personnel. The interpretation of automatically determined earthquake parameters in terms of the expected intensities in a given region and the probability of potential fatalities and damage is still a matter of experience and is not yet a matter of automatic calculations.

In practice, the around-the-clock human presence at the observatory is often achieved using all of the available, but mostly untrained, personnel in order to formally fulfill higher authorities' requirements. Of course, the actual value of such a 'solution' is questionable. If the alarms are of primary importance for a new network, one should consider using a system of a message on a mobile phone that will automatically alarm the institution's seismologists and give a first rough location and magnitude in the event of a strong earthquake. The seismologist should in turn be able to access the database remotely, if not living very closely

to the observatory, and interactively reassess and refine the first quick parameter estimates if required.

### **8.9.6.3 System maintenance**

Maintaining a seismic network's hardware and software is a continuous activity that inevitably requires well-trained personnel. Nowadays, many vital operational parameters and equipment health at seismic stations can be remotely monitored. Such parameters are for example: backup battery voltage, presence of charging voltage, potential software and communication problems, absolute time keeping, remote station vault and/or equipment temperature, potential water intrusion, etc. These utilities significantly reduce the need for field service work and therefore lower the cost of network operation. However, regular visits to the stations are still necessary, though far less frequently than in the past. Yet, once per year seems a minimum.

Note that it is a mistake to simply put off visits to remote seismic stations until something goes wrong. Periodic visual checks of cables and equipment, of potential corrosion problems on equipment and grounding and lightning system, and for intrusion of water and small animals are important. Batteries, burned lightning protection elements, and desiccants must be changed regularly, and cleaning the vaults and solar panels will also help to eliminate technical problems before they occur.

When something does go wrong, the technical staff must be certain that they can respond immediately with the right personnel, action, and spare parts. One should always maintain a good stockpile of the most common spare parts and have a well-trained technician with a pager on duty around the clock. Having technical personnel, in addition to seismologists, on call 24 hours a day for potential action is a good practice in the observatory seismology business, however this is rarely possible and not really necessary with most networks.

Operators of large networks may not have the manpower or budget resources to visit all of their stations annually. The major differences in maintenance procedures for small networks versus large regional or national networks are response time to site outages, site sensor-calibrations, and preventive maintenance (PM) visits. A large, dense seismic network lessens the need for 100% uptime for all sites; maintenance visits for site outages can be scheduled with PM visits in an area, something that a small, local network of 10 to 20 sites can not afford. This eliminates the need for immediate technician response and a 'beeper' for field repairs. For example: The U.S. Geological Survey's Northern California Seismic Network (NCSN), a large, dense regional network (352 analog and 93 digital stations), visits their telephone telemetered sites every 20 months and solar-powered sites every 4 years for site electronic equipment exchanges. These maintenance intervals are possible due to the robustness and reliability of their electronic amplifier/telemetry packages and associated equipments.

Be aware that batteries require special attention. If the lightning damages are the most frequent source of technical failures during normal operation conditions of a network, then battery failures will be the number one reason for failures during main power failures and unusually high-periods of seismicity. It should be noted that the output voltage alone of a battery provides little information about its overall health and capacity. Many types of batteries may still have adequate output voltage while at the same time their charge capacity is

reduced to a small fraction of its original strength. Batteries in this condition will not do the job in case of a long-duration power failure, as may occur after a damaging earthquake.

Ideally, all of the batteries in the seismic system should be laboratory tested once a year for their remaining charge capacity. The batteries should be fully discharged, then fully charged, and again discharged in a controlled manner and their true charge capacity determined. Once the measured charge capacity is less than 60% - 70% of their nominal capacity, they should be replaced with new ones. Relying solely on measurements of battery voltage will certainly lead to technical failures in the long run. The most important moment in the lifetime of the seismic network may happen only once a decade or less. One certainly does not want to miss it because of old batteries with insufficient charge capacity!

However, large networks may again not be able to laboratory test each battery once per year. The NCSN exchanges batteries using an operational window system for battery life (based upon the quality and the replacement cost of the batteries used, and their long-term experience with battery lifetimes) rather than with annual testing and rejuvenation. Their operational window for solar-panel batteries is 4 years (Tom Burdette, personal communication, 2002).

Non-chargeable batteries, particularly the lithium type, should be replaced regularly, in accordance with the manufacturer's instructions, regardless of their output voltage at the moment of lifetime expiration.

#### **8.9.6.4 Sensor calibration**

Seismological observatories should calibrate all of the sensors in their seismic system regularly - ideally, once a year. Strictly speaking, only the seismic signals recorded between two successive sensor calibrations that show no significant change in the sensor frequency response function are completely reliable. Sensor and sensor calibration issues are also different for a dense network equipped with modern sensors. Modern sensors are very robust, and many broadband sensors have automatic self-leveling, self-correcting features that eliminate the need for annual calibrations. In addition, site electronics can be installed to provide regular, telemetered sensor tests for response and operation. These features, along with a dense network sensor configuration allow for sensors to be replaced and recalibrated on a regular schedule. For NCSN, the short-period sensors are replaced at 10-year intervals, unless a sensor fails beforehand. NCSN short-period sites have built-in calibrators that perform daily mass releases to test sensor operation and response (Tom Burdette, personal communication, 2002).

Seismic sensor calibration requires knowledge that often is not available locally. In digital seismology, the sensor transfer function representation in form of poles and zeros is most commonly used. Both issues are discussed in detail in Chapter 5 and the annexed Exercises and Program Descriptions. A comprehensive description of basics is also given in Scherbaum (1996, 2001, and 2007). A description of a popular seismometer calibration program UNICAL is given in Plešinger et al. (1995).

#### 8.9.6.5 Archiving seismic data

After several decades, or even years, of operating a seismic network, the scientific and financial value of the recorded data is extremely high. Therefore, full attention must be paid to data archiving and a failsafe backup of the data. Seismology is a typical non-experimental science and lost or corrupted seismic data can never be regenerated. It is therefore an absolute must to provide a complete and reliable backup archive. The backups should be kept in a different physical location, no matter whether they are on paper, tape, disk, CD or other memory medium. Today, most networks record continuously giving very large data sets and one carefully needs to consider the backup options. Whenever possible, one copy (or the originals) should be stored in fire-resistant cabinets or safes. It is important to note that microfiche, film, and computer media require more protection than paper records. Paper records can withstand temperatures to 177°C (350°F), but computer media is damaged beyond use by temperatures above 52°C (125°F) and 80% humidity.

When one first sets up a seismic network, one needs to think thoroughly about organizing the data that is recorded in light of the fact that eventually the network will have many, many years of accumulated records. Often, this crucial aspect of seismic system organization is overlooked or left to on-the-spot decisions by whoever is in charge of the initial network operation. This may work fine for a while, but eventually everybody will run into serious problems if the archiving system chosen is inappropriate. It is necessary to carefully think through the archiving organization at the outset and to keep the long-term future in mind. At the same time archiving systems will be outdated in 5-10 years, and one has to be prepared to change to new systems regularly.

In a small, weak-motion network in a region of low seismicity that generates only a small number of events records each year, or in a small or medium size strong motion network, one can probably get by with a directory tree organization for the data archive, particularly if only event data is stored. However, it is now more common also for small networks to record continuously. Nevertheless, filename coding of events must be thoroughly thought out to avoid confusion and/or file name duplications. File names also should reflect complete date and time of each event. Larger networks in moderate to high seismicity regions might require a better-organized, relational database for archiving purposes. One should carefully consider the various options used by other seismological observatories and those available on the market before the network starts recording data. It is very painful to change the data coding or archiving method after several years of network operation, once thousands upon thousands of records are already stored. Today, the most common format for data storage is MiniSEED.

Very powerful professional databases may not be the most suitable choice for smaller networks, primarily due to their high initial and annual maintenance cost, and secondly, due to too many expensive build-in utilities which will never be used in seismology. However, they are the only choice for larger data centers with 1,000s of real-time channels. Special databases which have been developed by the seismological community for the needs of seismology, thoroughly tested in several existing applications, and accepted by many, seem to be the best choice at the moment.

If possible, it is advisable to keep the raw seismic data as produced by the digitizer (raw event files, or sequences of continuous data) in the archive along with the full documentation about the recording conditions (data acquisition parameters and accompanying information).

Processing and seismic analysis methods will change and evolve as time passes, so it can be useful to go back.

#### **8.9.6.6 Dissemination of seismic data**

International cooperation in the dissemination of seismic data is another prerequisite for the high-quality operation of any new seismic network. Broad-minded data sharing is the best way for a less experienced institution to get feedback about the quality of its own work and is also a widely accepted international obligation. Data formats for parameter and waveform data exchange are dealt with in Chapter 10.

The Internet is nowadays the most common way to disseminate earthquake information and waveform data through email, web-pages, etc. Other forms of communication such as fax, pager, mobile phone are also used for earthquake alert purposes. Some of the currently most relevant and often used Internet addresses of global, regional and national seismological data centers can also be found and directly linked via <http://www.szgrf.brg.de> and <http://www.seismo.ethz.ch/seismosurf/seismobig.html>.

Everyone can greatly improve their own work by observing and comparing their phase readings, event locations, magnitude determinations and source mechanism results with the results of others published in national or international seismological bulletins. Any seismic study should also include as much seismic information as possible from the neighboring regions and countries. Not only one's own data, but also all available pertinent data from others should be used in seismic research work. Disseminating one's own data will, in turn, facilitate easy and fast accessibility of data from others. It's very important to establish a generous data sharing relationship with other seismological institutions.

The U.S. Geological Survey National Earthquake Information Center (<http://neic.usgs.gov>) compiles data contributed from networks located around the globe in order to determine, as rapidly and as accurately as possible, the location and size of all destructive earthquakes that occur worldwide. This information is disseminated immediately to concerned national and international agencies, scientists, and the general public. The NEIC collects and provides to scientists and to the public an extensive seismic database that serves as a solid foundation for scientific research, principally through the operation of modern digital national and global seismograph networks and through cooperative international agreements. Similar services are provided by a number of agencies around the world.

Data from the NEIC is transferred to the International Seismological Centre (ISC) (<http://www.isc.ac.uk/>) for final bulletin creation about two years behind real time. The International Seismological Centre is a non-governmental organization charged with the final collection, analysis and publication of standard earthquake information from all over the world. Earthquake readings are received from almost 3,000 seismograph stations representing every part of the globe. The Center's main task is to re-determine earthquake locations making use of all available information, and to search for new earthquakes, previously unidentified by individual agencies.

Besides these global data centers for parametric data, there are many national, regional or global centers that provide access to seismological waveform data. Examples of global data centers are IRIS, GEOFON and GEOSCOPE, Data is also available from regional networks

such as MEDNET or nationally operating networks, e.g. GRF/GRSN (see 8.7.5), ICC etc. Suitable starting links are provided, e.g., from the web sites of the US Advanced National Seismic System (<http://www.anss.org/>) and of the Observatories and Research Facilities for European Seismology (ORFEUS) (<http://orfeus.knmi.nl>).

Traditionally, seismic observatories of national seismic networks or larger regional networks regularly publish preliminary seismological bulletins (weekly, or monthly), final seismological bulletins (yearly), and earthquake catalogs of the country or region (yearly, but with a few years delay so that the data from all other external sources can be included in the analysis). These catalogs are one of the bases for earthquake hazard assessment and for risk mitigation studies.

## Acknowledgments

The authors and the Editor are very thankful to John Lahr and Kent Fogleman of the USGS for their careful English prove-readings and complementary remarks that have helped to improve the original draft. Thanks go Egill Hauksson for contributing a new text and figure on the California Integrated Network, to Shin Aoi for providing an updated text and figure on the Japanese Seismic Networks, to Klaus Stammer for updating text and figure for the German seismic networks that transmit their data for joint processing at the BGR in Hannover, and to Liu Ruifeng for making available the new Fig. 8.16 and an extended power point presentation which allowed us to produce the summary text in section 8.7.4, which has been authorized by Liu Ruifeng.

## 1 Introduction

By introducing digital seismic data acquisition, long-term continuous recording and archiving of seismic signals has become a demanding technical problem. A seismic network or even a single seismic station operating continuously at high sampling frequency produces an enormous amount of data, which is often difficult to store (and analyze) locally or even at the recording center of a network. This situation has forced seismologists to invent triggered seismic data acquisition. In a triggered mode, a seismic station or a seismic network still process all incoming seismic signals in real time (or in near-real-time) but incoming data is not stored continuously and permanently. Processing software - a trigger algorithm - serves for the detection of typical seismic signals (earthquakes, controlled source seismic signals, underground nuclear explosion signals, etc.) in the constantly present seismic noise signal. Once an assumed seismic event is detected, recording and storing of all incoming signals starts. It stops after trigger algorithm 'declares' the end of the seismic signal.

Automatic trigger algorithms are relatively ineffective when compared to a seismologist's pattern recognition ability during reading of seismograms, which is based on years of experience and on the enormous capability of the human brain. There are few exceptions, where the most complex detectors, mostly dedicated to a given type of seismic signals, approach to human ability. In all practical cases, automatic trigger loose some data on one side and generate falsely triggered records, which are not seismic signals, on the other. Small

amplitude seismic signals are often not resolved from seismic noise and are therefore lost for ever, and, if the trigger algorithm is set sensitively, false triggers are recorded due to irregularities and occasionally excessive amplitude of seismic noise. False triggers burden off-line data analysis later and unnecessarily occupy data memory of a seismic recording system. As a result, any triggered mode data acquisition impairs the completeness of the recorded seismic data and produces some additional work to delete false records.

Several trigger algorithms are presently known and used - from a very simple amplitude threshold type to the sophisticated pattern recognition, adaptive methods and neural network based approaches. They are based on the amplitude, the envelope, or the power of the signal(s) in time domain, or on the frequency or sequency domain content of seismic signal. Among the more sophisticated ones, Allan's (1978; 1982) and Murdock and Hutt's (1983) trigger algorithms are probably the most commonly known. Many of these algorithms function in association with the seismic phase time picking task. Seismic array detection algorithms fall into a special field of research, which will not be discussed here. For more advanced algorithms see, e.g., Joswig (1990; 1993; 1995). However, in practice, only relatively simple trigger algorithms have been really broadly accepted. and can be found in seismic data recorders in the market and in most network's real time processing packages.

The simplest trigger algorithm is the amplitude threshold trigger. It simply detects any amplitude of seismic signal exceeding a pre-set threshold. The recording starts whenever this threshold is reached. This algorithm is rarely used in weak-motion seismology but it is a standard in strong motion seismic instruments, that is in systems where high sensitivity is mostly not an issue, and where consequently man-made and natural seismic noise amplitudes are much smaller than the signals which are supposed to trigger the instrument.

The root-mean-square (RMS) threshold trigger is similar to the amplitude threshold algorithm, except that the RMS values of the amplitude in a short time window are used instead of 'instant' signal amplitude. It is less sensitive to spike-like man-made seismic noise, however it is rarely used in practice.

Today, the 'short-time-average through long-time-average trigger' (STA/LTA) is the most broadly used algorithm in weak-motion seismology. It continuously calculates the average values of the absolute amplitude of a seismic signal in two consecutive moving-time windows. The short time window (STA) is sensitive to seismic events while the long time window (LTA) provides information about the temporal amplitude of seismic noise at the site. When the ratio of both exceeds a pre-set value, an event is 'declared' and data starts being recorded in a file.

Several more sophisticated trigger algorithms are known from literature (e.g., Joswig 1990; 1993; 1995) but they are rarely used in the seismic data loggers currently in the market. Only some of them are employed in the network's real time software packages available. When in the hands of an expert, they can improve the events/false-triggers ratio significantly, particularly for a given type of seismic events. However, the sophisticated adjustments of operational parameters to actual signals and seismic noise conditions at each seismic site that these triggers require, has proven unwieldy and subject to error in practice. This is probably the main reason why the STA/LTA trigger algorithm still remains the most popular.

Successful capturing of seismic events depends on proper settings of the trigger parameters. To help with this task, this Information Sheet explains the STA/LTA trigger functioning and gives general instructions on selecting its parameters. Technical instructions on setting the trigger parameters depend on particular hardware and software and are not given here. Refer to the corresponding manuals for details.

## 2 Purpose

The short-time-average/long-time-average STA/LTA trigger is usually used in weak-motion applications that try to record as many seismic events as possible. These are the applications where the STA/LTA algorithm is most useful. It is nearly a standard trigger algorithm in portable seismic recorders, as well as in many real time processing software packages of the weak-motion seismic networks. However, it may also be useful in many strong motion applications, except when interest is limited to the strongest earthquakes.

The (STA/LTA) trigger significantly improves the recording of weak earthquakes in comparison with amplitude threshold trigger algorithms. At the same time it decreases the number of false records triggered by natural and man-made seismic noise. To some extent it also allows discrimination among different types of earthquakes.

The STA/LTA trigger parameter settings are always a tradeoff among several seismological and instrumental considerations. The goal of searching for optimal parameter settings is the highest possible seismic station sensitivity for a given type of seismic signal (which may also include the target 'all earthquakes') at a still tolerable number of false triggers.

The STA/LTA trigger is most beneficial at seismically quiet sites where natural seismic noise (marine noise) is the dominant type of seismic noise. It is also effective in case of changes of 'continuous' man-made seismic noise. Such changes, for example, occur due to day/night variation of human activity nearby or in urban areas. The STA/LTA algorithm is less effective in the presence of irregular, high amplitude man-made seismic noise which is often of burst and/or spike type.

## 3 How it works - basics

The STA/LTA algorithm continuously keeps track of the always-present changes in the seismic noise amplitude at the station site and automatically adjusts the seismic station's sensitivity to the actual seismic noise level. As a result, a significantly higher sensitivity of the system during seismically quiet periods is achieved and an excessive number of falsely triggered records is prevented, or at least mitigated, during seismically noisy periods. Calculations are repeatedly performed in real time. This process is usually taking place independently in all seismic channels of a seismic recorder or of a seismic network.

The STA/LTA algorithm processes filter seismic signals (see section 5.1 'Selection of trigger filters' in this Information Sheet) in two moving time windows – a short-time average window (STA) and a long-time average window (LTA). The STA measures the 'instant' amplitude of the seismic signal and watches for earthquakes. The LTA takes care of the current average seismic noise amplitude.

First, the absolute amplitude of each data sample of an incoming signal is calculated. Next, the average of absolute amplitudes in both windows is calculated. In a further step, a ratio of both values — STA/LTA ratio—is calculated. This ratio is continuously compared to a user selected threshold value - STA/LTA trigger threshold level. If the ratio exceeds this threshold, a channel trigger is declared. A channel trigger does not necessarily mean that a multi-channel data logger or a network actually starts to record seismic signals. All seismic networks and most seismic recorders have a 'trigger voting' mechanism built in that defines how many and which channels have to be in a triggered state before the instrument or the network actually starts to record data (see section 5.4 below - 'Selection of voting scheme parameters'). To

simplify the explanation, we shall observe only one signal channel. We will assume that a channel trigger is equivalent to a network or a recorder trigger.

After the seismic signal gradually terminates, the channel detriggers. This happens when the current STA/LTA ratio falls below another user-selected parameter - STA/LTA dettrigger threshold level. Obviously, the STA/LTA dettrigger threshold level should be lower (or rarely equal) than the STA/LTA trigger threshold level.

In addition to the data acquired during the 'trigger active' time, seismic networks and seismic recorders add a certain amount of seismic data to the event file before triggering – pre-event-time (PEM) data. After the trigger active state terminates, they also add post-event-time (PET) data.

For better understanding, Figure 1 shows a typical local event and the trigger variables (simplified) during STA/LTA triggering.

**Figure 1** Function and variables of STA/LTA trigger calculations (see text for explanations).

Graph a) shows an incoming continuous seismic signal (filtered); graph b) shows an averaged absolute signal in the STA and LTA windows, respectively, as they move in time toward the right side of the graph; and graph c) shows the ratio of both. In addition, the trigger active state (solid line rectangle), the post-event time (PET), and the pre-event time (PEM) (dotted line rectangles) are shown. In this example, the trigger threshold level parameter was set to 10 and the dettrigger threshold level to 2 (two short horizontal dotted lines). One can see that the trigger became active when the STA/LTA ratio value exceeded 10. It was deactivated when the STA/LTA ratio value fell below 2. On graph d) the actually recorded data file is shown. It includes all event phases of significance and a portion of the seismic noise at the beginning.

In reality, the STA/LTA triggers are usually slightly more complicated, however, the details are not essential for the understanding and proper setting of trigger parameters.

## 4 How to adjust STA/LTA trigger parameters

To set the basic STA/LTA trigger algorithm parameters one has to select the following:

- STA window duration
- LTA window duration
- STA/LTA trigger threshold level
- STA/LTA detrigger threshold level.

However, optimal triggering of a seismic recorder or a seismic network does not depend only on these parameters. There are usually four additional associated parameters which, only if well tuned with the trigger parameters, guarantee optimal data recording. These parameters are:

- trigger filters
- pre-event time (PEM)
- post-event time (PET)
- trigger voting scheme.

Although not directly related to the STA/LTA trigger algorithm, these additional parameters are also be discussed below in order to provide a complete information.

The STA/LTA trigger parameter and associated parameters' settings depend on the goal of the application, on the seismic noise condition at the site, on the properties of seismic signals at a given location, and on the type of sensor used. All these issues vary broadly among applications and among seismic sites. Obviously, there is no general, single rule on setting them. Each application and every seismic site requires some study, since only practical experience enables the determination of really optimal trigger settings.

Note that seismic recorders and network software packages come with a set of default (factory set) trigger and trigger associated parameter values. They are rarely optimal and must therefore be adjusted to become efficient in a particular application. For best results, changing these parameters and gradually finding the best settings is a process which requires a certain amount of effort and time.

### 4.1 Selection of short-time average window (STA) duration

Short-time average window measures the 'instant' value of a seismic signal or its envelope. Generally, STA duration must be longer than a few periods of a typically expected seismic signal. If the STA is too short, the averaging of the seismic signal will not function properly. The STA is no longer a measure of the average signal (signal envelope) but becomes influenced by individual periods of the seismic signal. On the other hand, STA duration must be shorter than the shortest events we expect to capture.

To some extent the STA functions as a signal filter. The shorter the duration selected, the higher the trigger's sensitivity to short lasting local earthquakes compared to long lasting and lower frequency distant earthquakes. The longer the STA duration selected, the less sensitive it is for short local earthquakes. Therefore, by changing the STA duration one can, to some extent, prioritize capturing of distant or local events.

The STA duration is also important with respect to false triggers. By decreasing the duration of the STA window, triggering gets more sensitive to spike-type man-made seismic noise, and vice versa. Although such noise is usually of instrumental nature, it can also be seismic. At the sites highly polluted with spike-type noise, one will be frequently forced to make the STA duration significantly longer than these spikes, if false triggers are too numerous. Unfortunately, this will also decrease the sensitivity of the recording to very local events of short duration. Figure 2 explains the effect of STA duration on local events and spike-type noise.

**Figure 2** Influence of STA duration on trigger sensitivity to short local events and 'spiky' noise in seismic signals.

On graph a) a signal with an instrumental spike on the left and with a short, very local earthquake on the right side is shown. Graphs b) and c) show STA, LTA, STA/LTA ratio, and trigger active states along with PEM and PET. The STA/LTA trigger threshold was set to 10 and dettrigger threshold to 2. One can see that when using a relatively long STA of 3 sec, the earthquake did trigger the system, but only barely. However, a much bigger amplitude (but shorter) instrumental spike did not trigger it. The STA/LTA ratio did not exceed the STA/LTA threshold and there was no falsely triggered record due to the spike. The lower two

graphs show the same variables but for a shorter STA of 0.5 sec. The spike clearly triggered the system and caused a false record. Of course, the earthquake triggered the system as well.

For regional events, a typical value of STA duration is between 1 and 2 sec. For local earthquakes shorter values around 0.5 to 0.3 s are commonly used in practice.

#### 4.2 Selection of long-time average window (LTA) duration

The LTA window measures average amplitude seismic noise. It should last longer than a few 'periods' of typically irregular seismic noise fluctuations. By changing the LTA window duration, one can make the recording more or less sensitive to regional events in the 'Pn'-wave range from about 200 to 1500 km epicentral distance. These events typically have the low-amplitude emergent Pn- waves as the first onset. A short LTA duration allows the LTA value more or less to adjust to the slowly increasing amplitude of emergent seismic waves. Thus the STA/LTA ratio remains low in spite of increasing STA (nominator and denominator of the ratio increase). This effectively diminishes trigger sensitivity to such events. In the opposite case, using a long LTA window duration, trigger sensitivity to the emergent earthquakes is increased because the LTA value is not so rapidly influenced by the emergent seismic signal, allowing Sg/Lg waves to trigger the recording. Figure 3 explains the described situation.

**Figure 3** Influence of LTA duration on trigger algorithm sensitivity to earthquakes with emergent seismic signals.

In graph a) an event with emergent P waves is shown. Graphs b) and c) show the time course of trigger parameters for a relatively long LTA of 60 sec. The LTA does not change fast,

allowing the STA/LTA ratio to exceed the STA/LTA trigger threshold (short horizontal dotted line) and a normal record results. Graphs d) and e) show the same situation with a shorter LTA of 30 s. The LTA value increases much faster during the initial phase of the event, thus decreasing the STA/LTA ratio value which does not exceed the STA/LTA trigger threshold. No triggering occurs and the event is missed.

Similarly, efficient triggering of recording of events with weak P waves compared to S waves requires a longer LTA for two reasons. First, if P waves do not trigger, they 'contaminate' true information about seismic noise prior to the event measured by LTA, since their amplitude exceeds the amplitude of seismic noise before the event. This results in diminished trigger sensitivity at the moment when S waves arrive. This 'contamination' is decreased if a longer LTA duration is selected. Second, longer LTA makes the trigger more sensitive to P waves as well, if they are not strictly of impact type.

Figure 4 represents such a case. Graph a) shows a typical event with significantly bigger later phase waves than P waves. Graphs b) and c) show trigger parameters for a long LTA of 100 s. P wave packet as well as S wave packet trigger the recorder. Appropriate PEM and PET assure that the event is recorded as a whole in a single file with all its phases and a portion of seismic noise before them. Graphs d) and e) show the same situation but for a shorter LTA of 45 sec. One can see that the P waves did not trigger at all, while the S waves barely triggered. The STA/LTA ratio hardly exceeds the STA/LTA trigger threshold. As the result, the recorded data file is much too short. P waves and information about seismic noise before them are missing in this record. A slightly smaller event would not trigger at all.

**Figure 4** Influence of LTA duration on trigger algorithm sensitivity to earthquakes containing weak P waves.

On the other hand, a short LTA will successfully accommodate recorder sensitivity to gradual changes of 'continuous' man-made seismic noise. Such 'transition' of man-made seismic noise from low to high is typical for night-to-day transition of human activity in urban areas. Sometimes, using a short LTA can mitigate false triggers due to traffic. Examples of such cases could be a single heavy vehicle approaching and passing close to the seismic station on a local road, or trains on a nearby railway. A short LTA can 'accommodate' itself fast enough to such emerging disturbances and prevent false triggers.

Figure 5 shows an example of the LTA response to increased seismic noise. Graph a) shows seismic noise, which gradually increased in the middle of the record. Note that the change of its amplitude is not sudden but lasts about 20 to 30 sec. Graphs b) and c) show the situation at a short LTA of 30 sec. One can see that the LTA value more or less keeps track of the increased noise amplitude. The STA/LTA ratio remains well below the STA/LTA trigger threshold and there is no false trigger in spite of significantly increased seismic noise at the site. Graphs d) and e) show the situation with a longer LTA of 60 s. In this case, the LTA does not change so rapidly, allowing a higher STA/LTA ratio during noise increase. As the result, a false trigger occurs and a false record is generated which unnecessarily occupies data memory.

**Figure 5** Influence of LTA duration on false triggering when seismic noise conditions change.

Natural seismic noise (marine noise) can change its amplitude by a factor exceeding the value of twenty. However, these changes are slow. Significant changes can occur only during a few hours period, or at worst, in several tens of minutes. Therefore even the longest LTA duration is short enough to allow LTA to accommodate completely to marine noise amplitude variations.

The LTA duration of 60 seconds is a common initial value. A shorter LTA duration is needed to exclude emergent regional events from triggering, if desired, or if quickly changing man-made noise is typical for the site. A longer LTA can be used for distant regional events with very long S-P times and potentially emergent P waves.

### 4.3 Frozen versus continuously updated LTA during events

Calculations of the LTA value during an event, that is after a channel trigger is declared, can be performed in the first approximation in two different ways.

Either the LTA value is continuously updated and calculated during the event as usual, or the LTA value is kept frozen at the moment when channel trigger is declared. In this case the LTA is not allowed to change (increase) during an event at all. Most of seismic recorders available in the market have both frozen or continuously updated LTA user-selectable options. However, each approach has its good and bad points.

The 'frozen' LTA window (the word 'clamped' is also used in literature) can force the unit into a permanently triggered state in case of a sudden increase of man-made seismic noise at the site. The situation is illustrated in Figure 6.

Graph a) shows an earthquake during which seismic noise increases and remains high even after the termination of the event. Such a situation can happen if, for example, a machinery is switched on in the vicinity of the recorder. In such a case, a completely frozen LTA (graph b) would never again allow the STA/LTA ratio to fall below the STA/LTA det trigger threshold level (graph c) and a continuous record would result. The result is that the seismic recorder's memory soon gets full and blocks further data recording.

A continuously updated LTA (the word 'unclamped' is also used in literature), on the other hand, frequently terminates records too early. Graphs d) and e) of Figure 6 explain this situation. Very often records with truncated coda waves result because the LTA increases rapidly if the beginning portion of a large earthquake signal is included in its calculation. Thus the STA/LTA ratio decreases too rapidly and terminates recording prematurely. Coda waves of the event are then lost, as shown in the Figure 6. This undesired result could be even much more distracting for records of regional events with longer duration.

Some seismic recorders work with a special calculation of LTA. The LTA value is, to the first approximation, 'frozen' after a trigger. However, this 'freezing' is not made complete. Some 'bleeding' of event signal into the LTA calculation is allowed. Such an algorithm tries to solve both problems: it does not cause endlessly triggered records in the case of a rapid permanent increase of seismic noise and, at the same time, it does not cut coda waves too early.

**Figure 6** Potential problems with two conventional ways of calculating the LTA: an endless record with a completely frozen LTA and cut coda waves with updated LTA calculations.

#### 4.4 Selection of STA/LTA trigger threshold level

The STA/LTA trigger threshold level to the greatest extent determines which events will be recorded and which will not. The higher value one sets, the more earthquakes will not be recorded, but the fewer false-triggers will result. The lower the STA/LTA trigger threshold level is selected, the more sensitive the seismic station will be and the more events will be recorded. However, more frequent false triggers also will occupy data memory and burden the analyst. An optimal STA/LTA trigger threshold level depends on seismic noise conditions at the site and on one's tolerance to falsely triggered records. Not only the amplitude but also the type of seismic noise influence the setting of the optimal STA/LTA trigger threshold level. A statistically stationary seismic noise (with less irregular fluctuations) allows a lower STA/LTA trigger threshold level; completely irregular behavior of seismic noise demands higher values.

Note that some false triggers and some missed earthquakes are an inevitable reality whenever recording seismic signals in an event-triggered mode. Only a continuous seismic recording, if affordable, completely solves the problem of false triggers and incompleteness of seismic data.

It is a dangerous trap to select a very high STA/LTA trigger threshold level and a high channel gain simultaneously. Many recorders in the market allow this setting without any warning messages. This situation is particularly dangerous in extremely noisy environments, where, due to too many false triggers, the instruments are usually set to record only the strongest events.

Suppose one has set the STA/LTA trigger threshold level to 20. Suppose also that one has set the gain of the channel in such a way that it has about 150 mV of average seismic noise signal at the input of the recorder and the input full scale voltage of the channel is  $\pm 2.5$  V. Obviously, this setting would require a  $0.15 \text{ V} \times 20 = 3 \text{ V}$  signal amplitude to trigger the channel. Since its maximum input amplitude is limited to 2.5 V, it can never trigger, no matter how strong an earthquake occurs. Note that this error is not so obvious, especially in low seismicity regions with rare events. One can operate an instrument for a very long time without records and forever wait for a first recorded earthquake.

With certain products in the market, this potential danger of an erroneous setting is solved in the following way: whenever one uses the STA/LTA algorithm, an additional threshold trigger algorithm remains active in the 'background'. Because of it, the channel triggers whenever its input amplitude exceeds 50% of channel input voltage range, for example, in no relation to the STA/LTA trigger setting. In this way, the strongest and therefore the most important events are still recorded, no matter how carelessly the STA/LTA trigger algorithm parameters are set.

An initial setting for the STA/LTA trigger threshold level of 4 is common for an average quiet seismic site. Much lower values can be used only at the very best station sites with no man-made seismic noise. Higher values about 8 and above are required at less favorable sites with significant man-made seismic noise. In strong-motion applications, higher values are more common due to the usually noisier seismic environment and generally smaller interest in weak events.

#### **4.5 Selection of STA/LTA dettrigger threshold level**

The STA/LTA dettrigger threshold level determines the termination of data recording (along with the PET parameter – for more information see 5.3 below on “Selection of post-event time (PET) parameter”).

The STA/LTA dettrigger threshold level determines how well the coda waves of recorded earthquakes will be captured in data records. To include as much of the coda waves as possible, a low value is required. If one uses coda duration for magnitude determinations, such setting is obvious. However, a too low STA/LTA dettrigger threshold level is occasionally dangerous. It may cause very long or even endless records, for example, if a sudden increase in seismic noise does not allow the STA/LTA ratio to fall below the STA/LTA dettrigger threshold level. On the other hand, if one is not interested in coda waves, a higher value of STA/LTA dettrigger threshold level enables significant savings in data memory and/or data transmission time. Note that coda waves of distant earthquakes can be very long.

In general, the noisier the seismic site, the higher the value of the STA/LTA dettrigger threshold level should be used to prevent too long or continuous records. This danger is high only at sites heavily polluted by man-made seismic noise.

A typical initial value of the STA/LTA det trigger threshold level is 2 to 3 for seismically quiet sites and weak motion applications. For noisier sites higher values must be set. For strong-motion applications, where coda waves are not of the highest importance, higher values are frequently used.

## **5 How to adjust associated parameters for proper triggering and data recording**

### **5.1 Selection of trigger filters**

Nearly all seismic recorders and networks have adjustable band-pass trigger filters. They continuously filter the incoming seismic signals prior to the trigger algorithm calculations. Selection of these filters is important for a proper functioning of the STA/LTA trigger algorithm (as well as for amplitude threshold trigger algorithm). The purpose of these filters is three-fold:

- they remove DC component from incoming seismic signals, namely, all active seismic sensors have some DC offset voltage at the output which, if too high, deteriorates the STA/LTA ratio calculation. The calculation of the absolute value of the signal becomes meaningless if the DC component is higher than the seismic noise amplitude. This results in malfunction of the STA/LTA trigger algorithm and drastic reduction of trigger sensitivity for weak seismic events;
- their frequency band-pass can prioritize frequencies corresponding to the dominant frequencies of seismic events one wants to record; and
- their stop-band can attenuate dominant frequencies of the most distracting seismic noise at a given site.

The trigger filter pass-band should generally accommodate the frequencies of the maximum energy of expected seismic events. At the same time it should have a band-pass that does not coincide with peak frequency components of typical seismic noise at the site. If this is possible, a significant improvement of the event-trigger/false-trigger ratio results. Obviously, one can understand that if the peak amplitudes of seismic noise and the dominant frequencies of the events of most interest coincide, the trigger filter becomes inefficient.

One should not forget that the frequency response function of the seismic sensor used with a recorder or in a network channel also modifies the frequency content of events and noise signals at the input of trigger algorithm. Therefore the sensor used is an important factor in the choice of a trigger filter. The type of sensor output - proportional to either ground displacement, velocity or the acceleration - has a similar effect. Sensors with ground acceleration proportional output - accelerometers - emphasize high frequencies. They usually require a filter protection against excessive high-frequency man-made seismic noise. Ordinary seismometers have typically an output proportional to ground velocity, sometimes also to ground displacement and they are less influenced by high-frequency man-made seismic noise.

The adjustment flexibility of high- and low-corners of these filters varies among different products. The same is true for the steepness of the filter flanks. Generally, one does not need very steep (high order) filters and a lot of flexibility, because events, similar to the seismic noise, are highly variable. It is generally impossible to determine very precisely where exactly to set the frequency limits of these filters.

## 5.2 Selection of pre-event time (PEM ) parameter

Ideally, the triggered earthquake records should include all seismic phases of an event and, in addition, a portion of the seismic noise signal prior to it. Selection of an appropriate pre-event time (PEM) assures that the earthquake records are complete. For the majority of weak events, the trigger algorithm usually does not trigger at the beginning of the event but sometimes during the event, when the waves with the maximum amplitude of ground velocity reach the station. This happens very often with the earthquakes that have emergent onset waves, and with most of the weak local and regional events where the S phase amplitudes can be much bigger than the P phase. In practice, triggering on the S waves of the weak local and the regional earthquakes is actually more frequent than triggering on the P waves. But for seismological reasons, the P onset waves, plus some seismic noise prior to them, should be included in the record. A proper PEM should take care of this.

Technically this is solved in the following way. In seismic recorders and in a network's central recording computer, a portion of seismic signal prior to the instrument trigger time is temporarily stored in a pre-event ring buffer (abbreviation PEM denotes 'pre-event-memory') and added to the data recorded.

PEM must surmount the following periods of time:

- the desired record duration of seismic noise prior to the event;
- the maximal expected S-P time of earthquake records; and
- time needed to calculate the STA/LTA ratio, which, in the worst case, equals one STA window duration.

Add these three time periods and the result is the appropriate PEM value.

The effect of a too short PEM is shown in Figure 7. Graph a) shows an event approximately 400 km away from the station with weak P waves partly buried in the seismic noise. On graph b) the STA and the LTA values are shown. Graph c) shows the STA/LTA ratio and the trigger and det trigger thresholds (short horizontal dotted lines). The trigger threshold is set to 6.

One can see that the channel triggers on the S waves. However, a PEM of 10 seconds is much too short to catch the P waves. Graph d) shows the actually 'recorded' event. It starts much too late and contains no seismic noise record. Graphs e) and f) show the same event but with a properly set PEM parameter. Seismic noise as well as the P waves are properly recorded.

The maximum expected S-P time depends on the maximal distance of relevant earthquakes from the station and on seismic wave velocity in the region. For practice and for local and regional events, accurate enough results can be gained by dividing the maximum station-to-epicenter distance of interest by 5 (distance in miles) or by 8 (distance in km) to get the required maximum S-P time in seconds.

The application dictates the choice of the desired pre-event noise record duration. At least a few seconds are usually required. Note that if one wants to study spectral properties of weak events, seismic noise spectra are usually required to calculate signal-to-noise ratio as a function of frequency. This, however, requires a significant length of noise records depending on the lowest frequency of interest. The PEM must be set accordingly.

**Figure 7** Proper and improper setting of the pre-event time (PEM) and the post-event time (PET)

As an example, let us calculate a required PEM parameter value for a temporary local seismic network with 50 km aperture, where 0.5 sec is set for the STA duration. Suppose that no coincidence trigger exists and all stations run independent trigger algorithms. The operator of the network is interested in the seismicity 200 km around the center of the network. He would also like to have a 10 sec long record of seismic noise before the P waves. We need 0.5 sec for STA calculation, 10 sec for seismic noise, and  $\approx (200 \text{ km} + 50/2 \text{ km})/8 \approx 28 \text{ sec}$  to cover the maximum expected S-P time. Note that the most distant station from the epicenter in the network still has to record P waves — that is why we added one half of the network aperture to the maximum epicentral distance of interest. The PEM should therefore be set to  $0.5 + 10 + 28 \sim 40 \text{ sec}$ . Obviously, smaller networks and shorter ranges of interest require shorter PEM and vice versa.

### 5.3 Selection of post-event time (PET) parameter

The post-event time parameter assures complete recording of seismic events after a det trigger. The main purpose of PET is catching the remaining earthquake coda waves that are smaller in amplitude than the STA/LTA det trigger threshold level. Functionally PET is simply a fixed recording time added to the event file after an instrument or a network (not individual channels!) det triggers. It has a similar effect on coda waves as the STA/LTA det trigger threshold level parameter. However, its effect is event-size independent. This makes it a less effective coda wave 'catcher' than a low STA/LTA det trigger threshold level. It is most suitable for local events. Practical values of PET are usually too short to be of any help for large distant earthquakes with very long coda waves. Contrary to a very low STA/LTA det trigger threshold level that may cause re-triggering problems, a long PET is safe in this respect (see 4.5 above on "Selection of STA/LTA det trigger threshold level").

Optimal PET duration depends mostly on the application. If coda waves are important, a long PET should be selected. If coda waves have no significance, use a short PET. Obviously, the short local events require only a short PET, regional and teleseismic events, on the other hand, would require much longer PET.

A reasonable value for local seismology would be 30 sec, and 60 to 90 sec for regional seismology, assuming one wants the coda waves well recorded. To find optimal value, observe coda waves of your records and adjust the PET accordingly.

There are usually no practical instrumental limitations on selection of the longest PET. However, note that very long PETs use up the recorder's data memory easily. So, do not exaggerate, particularly in seismically very active areas or if a high rate of false triggers is accepted.

### 5.4 Selection of voting-scheme parameters

The coincidence trigger algorithm, available either in seismic networks or within a multi-channel stand-alone seismic recorder, or in a group of interconnected seismic recorders, uses voting scheme for triggering. The voting-scheme parameters are actually not directly related to the STA/LTA trigger algorithm. However, inappropriate setting of voting scheme prohibits efficient functioning of overall triggering of a network or a recorder. For that reason we also deal with the voting scheme parameters in this section.

In section 4 'How to adjust STA/LTA trigger parameters', we described how each individual channel would trigger if it were the only one in an instrument or in a network. In the following section we describe how the individual channel triggers are combined to cause the system to trigger in a multi-channel recorder or in a seismic network. We call this 'voting', as a number of votes or weights can be assigned to each seismic channel so that they may cause the system to trigger. Only if the total number of votes exceeds a given pre-set value, does the system actually trigger, a new data file opens, and data acquisition begins.

How this voting system is set up depends on the nature of the signals that one is trying to record and on the seismic noise conditions at sensor sites. The noisy channels, which would frequently falsely trigger, will obviously have less 'votes' or assigned weights than the quiet, 'reliable' channels. One will need some first-hand experience of the conditions at the sites before optimizing this voting scheme. The voting mechanism and the terminology differ to

some extent among products. However, there are usually four basic terms associated with the voting scheme parameters, namely:

- Channel weights (votes)

A channel weight defines the number of votes the channel contributes to the total when it is triggered. If the channel has a good signal/noise ratio, assign it a positive number of votes. The more 'reliable' the channel in terms of the event trigger/false trigger ratio is, the higher the number should be selected. If a channel is noisy and frequently falsely triggers, give it lesser or even zero weight. In case you want a channel to inhibit triggering (a rare case indeed), give it negative weights.

- Trigger weight

This is the total number of weights required to get the seismic recorder or the network to trigger.

- Detrigger weight

The Detrigger weight is a value below which the total trigger weights (sum of all individual weights) must fall in order to cause a recorder or a network to detrigger. The Detrigger weight of 1 usually means that all voting channels must be detriggered before the recorder will detrigger. However, other definitions are also possible.

- External channel trigger weight

This value represents the number of weights one assigns to the 'external trigger channel' source. This parameter is most useful in networks of interconnected stand-alone seismic recorders. In this configuration every triggered recorder 'informs' all other units in the network that it triggered. If one wants to ensure that all recorders in the network trigger when one unit triggers, the external trigger channel should have the same weight as the Trigger weight. If one wants to use a combination of an external trigger with other internal criteria, one should set the weights accordingly.

Understanding of the voting scheme parameters is best gained through examples. The following section gives a few examples of various voting schemes.

- A classic strong-motion seismic recorder set at a free-field site has no interconnected units and normally has a three-component internal FBA accelerometer. One would set all three Channel weights to 1 and also set the Trigger weight to 1. Consequently any channel could trigger the system. At noisier sites a Trigger weight set to 2 would be more appropriate. In the latter case, two channels must be in a triggered mode simultaneously (or within a time period usually named aperture propagation window (APW) time, which is an additional parameter available with seismic networks) for the beginning of data recording.
- A small weak motion seismic network around a mine is designed for monitoring local micro-earthquakes. It consists of 5 surface seismic stations with vertical component short-period seismometers and one three-component down-hole accelerometer. An 8-channel data logger is used at the network's center. One of the surface stations is extremely noisy due to nearby construction works. All others have approximately the same seismic noise amplitudes. One can temporally set a Channel weight 0 to the noisy station to exclude its contribution to triggering and channel weights of 1 to all other surface stations. The down-hole accelerometer is very quiet but

less sensitive than surface stations (accelerometers). Select Channel weight 2 for each of its components. For this network a trigger weight of 3 would be an adequate initial selection. The system triggers either if at least three surface stations trigger, or two components of the accelerometer trigger, or one surface station and one component of the accelerometer trigger. Suppose also that there are frequent blasts in the mine. If one wishes, one can use an External trigger channel weight set to -8 and manually (with a switch) prevent seismic network recording of these blasts (down-hole:  $3 \times 2$  channel votes + surface stations:  $4 \times 1$  channel vote - 8 External votes < 3 Trigger votes).

- Let us suppose that an interconnected strong motion network of two seismic recorders with the internal three-component FBA accelerometers is installed in a building, one in the basement and one on the roof. Initially one can set the Channel weights to 1 for each signal channel, as well as for the External trigger channel. Suppose the Trigger weight is set to 1 as well. As a result each channel of the system can trigger both units in the system.

After a while one discovers that the seismic recorder on the roof triggers the system much too frequently, due to the swaying of the building in the wind. Changing the voting scheme of the roof unit so that Trigger weight is 3, its channels have 1 weight, while the External trigger channel has 3 weights, can compensate for this action. Now, the recorder installed on the roof triggers only if all its three channels trigger simultaneously or if the 'quiet' recorder in the basement triggers. The number of falsely triggered records will be drastically reduced.

- A small regional radio-frequency (RF) FM modulated telemetry seismic network, with a coincidence trigger algorithm at the central recording site, has 7 short period three-component seismic stations. The three stations, #1 west of the center and #2 and #3 east, not far from the center, have a low seismic noise and are connected to the center via three independent reliable RF links. The two stations north to the center, #4 and #5, are linked with the center via a joined RF repeater. The link between this repeater and the center is, unfortunately, frequently influenced by RF interference, resulting in frequent and simultaneous spikes and glitches in all six transmitted seismic signals. Due to unfavorable geology these two stations have a relatively high seismic noise. The two stations south of the center, #6 and #7, are also connected to the center via another common RF repeater. The station #6 is very quiet and the station #7 is influenced by traffic on a nearby new busy freeway. The RF link from this repeater to the center is less RF interference prone.

In such a situation (apart from trying to technically solve the RF link problem with the northern stations and repositioning of the station #7) an appropriate initial voting scheme would be as follows. A Trigger weight set to 7 (to disable otherwise much too frequent false triggering of the system due to RF interference on all 6 channels of the two northern seismic stations) and a Channel weight 1 to all channels of the northern stations (their total Channel weight should not exceed the Trigger weight), a channel weight 3 to all three channels of the station #1 (to allow independent triggering of the system if all three channels of this good station are triggered), a channel weight 2 to all channels of the stations #2 and #3 (to allow triggering of the whole system if at least four channels of these two closely situated stations are activated), a channel weight 2 to all channels of the station #6 (to accentuate its low seismic noise characteristics but to prevent independent triggering of the system due to occasional RF interference), and a weight 0 to all channels of the station #7 (to exclude its partition in triggering due to excessive man-made seismic noise).

These examples should give enough insight into the flexibility of the coincidence triggering options and about some of the ways in which this flexibility can be used for a particular application. Note also that any initial voting scheme can be significantly improved after more experience is gained with seismic noise conditions at the sites.

## 6 Practical recommendations for finding optimal triggering parameters

A systematic approach is required for successful adjustment of the optimal triggering and the associated parameters. First, the goals of the seismic installation must be carefully considered and *a priori* knowledge about seismic noise (if any) at the site(s) must be taken into account. Based on this information, the initial parameters are set. Information about them must be saved for documentation purpose. Start with rather low trigger threshold level settings than with a too high setting. Otherwise one can waste too much time in getting a sufficient number of records for a meaningful analysis required for further adjustment steps.

Then the instrument or the network is left to operate for a given period of time. The required length of operation without changing recording parameters depends strongly on the seismic activity in the region. At least several earthquakes and/or falsely triggered records must be recorded before the first readjustment of parameters is feasible. Judgments based on a single or a few records rarely lead to improvements. Such work simply doesn't arrive at any meaningful adjustment.

Afterwards, all records, including those falsely triggered, must be inspected. The completeness of the event records is checked (seismic noise, the P arrivals, the coda waves), and the causes of the false triggers are analyzed. The ratio of event-records/false-records is calculated and compared to the target level. If the number of false triggers does not reach the accepted level, increase the trigger sensitivity by lowering the STA/LTA trigger threshold level(s). Basically, one will acquire more seismic information for nearly the same price and effort. If the number of false triggers is too high, find the reasons why and try to mitigate them by changing STA/LTA and/or voting scheme parameters. Only if this doesn't help, must one decrease trigger sensitivities.

After the analysis is finished, the parameters are changed according to its findings and the new settings archived for documentation purposes. Again the instrument or the network is left active for a certain period of time, the new records are analyzed, and other changes made if needed. By repeating this process one will gradually find the best parameter setting.

## 1 Introduction

With the rapid development of communication technology, especially in the area of satellite communication, new possibilities arise for the design and implementation of seismic networks. A decade ago, the only financially appropriate solution to integrate seismic stations into a network was often the use of terrestrial wireless links, such as radio frequency telemetry systems. These systems, although good value for money, are usually limited by their maximum link distance and their data throughput. As prices for satellite-based communication services have dropped drastically, these services have become a widely used alternative for largely distributed seismic networks.

This Information Sheet provides a short overview of a range of communication systems useful in remote areas where regular Internet access or dial-up phone lines are not available.

Some turnkey solutions for seismic networks are commercially available and most already integrate a communication system (e.g. Libra VSAT provided by Nanometrics) to avoid extensive analysis and design work by the customer. This has advantages and disadvantages (see 8.8.4). The communication system is well optimized for seismic data transmission for the manufacturers turnkey solution, but usually lacks flexibility.

This Information Sheet aims to support the requirements analysis, the design phase and the selection process when upgrades of existing seismic networks or new installations are planned without using a turnkey solution. Communication technologies and their relevant characteristics are briefly compared with emphasis on practical aspects.

Finally, Appendix 1 provides a quick network design schema using the information provided in this sheet and Appendix 2 a list of manufacturers and products the reader may refer to for further information.

## 2 Requirements analysis

Generally the selection process is a trade-off between requirements driven by the application of the seismic data, characteristics of available communication systems and most importantly financial constraints of the project. Cost aspects are usually in focus; however, it is of very high importance to thoroughly understand the requirements of the application for the seismic network before making a good choice. When designing a seismic network the relevant points to be considered with respect to the communication system are the following:

- Are seismic data needed in near real-time or downloaded at defined intervals?
  - Type of communication link needed (permanent online and streaming or dial-up and file-based transmission)
- Is the network a temporary or permanent deployment?
  - Equipment transportation and installation efforts/ costs
- What are the requirements regarding resolution and sampling rate of the waveforms?
  - Data rate limits and operational costs
- How wide is the geographical distribution of the stations?
  - Link distance limits and coverage area
- How remote are the stations?
  - Communication systems availability at site
  - Travel and transportation costs
  - Power supply investments for communication system
  - Back-up communication system for troubleshooting
- What are the availability constraints of the network (especially during natural disasters)?
  - Shared vs. dedicated links
  - Terrestrial vs. satellite based systems
  - Back-up communication system
- Are there data security requirements?
  - Encryption and authentication support
- Last but not least: what is the project budget?
  - Hardware costs
  - Operational costs
  - Transportation costs

- o Power supply investments
- o Travel and maintenance costs

Nowadays, with the increasing demand for high-quality seismic data for both, pure scientific detailed studies as well as early warning and rapid response networks, the communication system is becoming a key feature of a seismic station. In particular, different applications in seismology will impose different requirements on the communication infrastructure. A simplified list of the main seismological applications and their peculiarities, with respect to the points listed in the previous paragraph, is:

1. **Early warning systems** – permanently installed with real-time data delivery to send out timely warnings to the population as a national service (e.g. for earthquakes, tsunami, volcanic eruptions, landslides, etc.). The stations are generally located in very remote areas. Latency of the communication system technology may become an issue for on-site early warning (50 km leads to approximately 6 seconds time between the first P phase and the following destructive S phase). For other natural hazards, generally the warning time is not so short and latency of the communication technique used is not an issue.
2. **Rapid response, earthquake monitoring networks** – the aim of this network type is to have quick parameterization of an earthquake (location, magnitude, shake map) and fast earthquake parameters dissemination. Generally the earthquake information should be disseminated within few minutes from the origin time. Depending on the dimension of the target seismogenic area (local, regional or global), the size of the network and the dissemination time frame may vary.
3. **Emergency deployments** – after disastrous events, seismologists generally increase the number of stations with dense temporary deployments near the epicentre to have a better characterization of the rupture that generated the earthquake, as well as to investigate site effects. In the past, this task was generally done offline. Nowadays, with better integration among rescue teams and seismologists dedicated to emergency deployments, the real-time communication may be useful to follow the aftershock sequence evolution and even predict its evolution. Moreover, real-time state of health monitoring of buildings may be done especially for critical infrastructures (i.e. hospitals, bridges, tunnels, pipelines, etc.)
4. **Building monitoring** – besides the state of health monitoring done in emergency deployments, in some countries exposed to a high earthquake hazard, it is becoming a standard practice to continuously monitor the state of health of critical infrastructures in real-time and follow its state of health during large earthquakes. Moreover, engineers also perform offline data acquisition on buildings in order to better understand their behaviour.
5. **Seismic arrays and micro-arrays** – these are generally small seismic networks installed to have a detailed investigation of small scale phenomena. They may be used to investigate small earthquake swarms, induced seismicity, seismic noise, etc. In general, they do not require continuous real-time links, but for some applications (expected induced seismicity) the network operator may demand the real-time acquisition and processing.

Table 1 provides a schematic overview of the main seismological applications discussed above with respect to their communication systems requirements.

**Table 1** Comparative matrix for applications based on seismic networks. Please note that for large events, the rupture area may go beyond the indicated geographic spread of the network.

| Application Type                | Scale    | Geographic Spread | Sampling/<br>Data Rates                 | Link Type                                  | Required Robustness | Remoteness of Stations                         |
|---------------------------------|----------|-------------------|-----------------------------------------|--------------------------------------------|---------------------|------------------------------------------------|
| Early Warning                   | Local    | <100 km           | High for local and low for global scale | Continuous link for real-time data streams | Very high           | Remote                                         |
|                                 | Regional | <1000 km          |                                         |                                            |                     |                                                |
|                                 | Global   | Global            |                                         |                                            |                     |                                                |
| Rapid Response                  | Local    | <100 km           | High for local and low for global scale | Continuous link for real-time data streams | High                | Remote                                         |
|                                 | Regional | <1000 km          |                                         |                                            |                     |                                                |
|                                 | Global   | Global            |                                         |                                            |                     |                                                |
| Emergency Deployments           | Local    | <500 km           | Very high/High                          | Offline, dial-up or real-time streaming    | High if real-time   | Depend on EQ location (in general urban areas) |
| Building Monitoring             | Local    | <10 km            | Very high                               | Offline, dial-up or real-time streaming    | High if real-time   | Urban areas                                    |
| Seismic Arrays and Micro-Arrays | Local    | ~100 km           | Very high/high                          | Offline or real-time streaming             | Low                 | Depend on the target area                      |

### 3 Design of a communication system for a seismic network

All applications discussed in the previous paragraph have one thing in common: there is a central storage facility to collect and process the data of all stations. This facility is usually located at a data centre or is simply a central computer installed remotely in the field. It is important to be clear about the data flow of the network in order to select a suitable topology to accommodate the general requirements.

Each network topology has advantages and disadvantages (Table 2). These should be mapped against the requirements of the seismological application in order to optimize data flows. Often a combination of different topologies provides the optimal result, but hybrid topologies are more complex to troubleshoot and maintain. This can lead to higher maintenance costs. To design the network, a topology map should be drafted, indicating link distance and, if not uniform, the amount of data transmitted on each link. The data rate estimation must consider the number of sensors and components at each station, applied sampling rates, and resolution of the digitizer. Data acquisition protocols, such as SeedLink, may improve the efficiency in data transmission, depending on the compression algorithm used. (see 8.6.6). The draft should also indicate if the link needs to be available permanently or if a dial-up link is sufficient.

In addition to the inter-station network, each single station also has an internal- or intra-station network to connect digitizers with other local hardware (i.e., a local computer as data-buffer), as well as to the communication gateway on site (Figure 1). The gateway is the element of the

network connecting intra-station and inter-station networks. The intra-station network is usually not very complex. Sensors should be installed in separate compartments from the rest of the equipment, but generally they are in close proximity to each other (see 7.4). However, borehole installations or sensor installations in caves or mines can lead to challenging requirements. Depending on the individual conditions, this can require special solutions for the intra-station communication system. This Information Sheet also describes technical alternatives that can cover larger distances between the equipment on-site in case it is needed.

**Table 2** Network topologies: nodes represent stations and lines the communication links. For data rates we assumed uniform station setup.

| Topology              | Line                                                                              | Star                                                                              | Tree                                                                               | Mesh                                                                                       |
|-----------------------|-----------------------------------------------------------------------------------|-----------------------------------------------------------------------------------|------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------|
| Map                   |  |  |  |         |
| Maximum Link Distance | Short                                                                             | Large                                                                             | Short                                                                              | Large                                                                                      |
| Data Rates            | Data rate differs on each link                                                    | Equal data rates on each link                                                     | Data rates can differ                                                              | Data rates can differ                                                                      |
| Efficiency            | Data exchanged between stations has to travel through other nodes                 | Data exchanged between stations has to travel through central node                | Data exchanged between stations has to travel through other nodes                  | Direct data exchange between stations possible                                             |
| Robustness            | Weak, a link outage can effect more than one node                                 | Robust, a link outage only effects one node                                       | Weak, a link outage can affect more than one node                                  | Very robust, a link outage will not affect availability (using dynamic routing algorithms) |

**Figure 1** Schematic representation of an intra-station network, which connects the equipment at one seismic station, and the inter-station network combining all stations to one seismic network.

Independent of the implementation of the physical network links, the logical network design of the overall network should be planned very carefully. Addressing schemes can be based on public or private IP address ranges (Rekhter et al., 1996). Public IP addresses are assigned by

the Internet Corporation for Assigned Names and Numbers (ICANN, <http://www.icann.org/>) and are guaranteed to be globally unique to enable routing of data packets via the Internet. Usually public IP ranges are rented from Internet service providers (ISP), which implies an additional monthly service charge. If stations do not need Internet access and data is exchanged with the central node only, the use of private IP ranges can reduce operational costs and increase security, as well as reliability.

In a common scenario, each station runs its own private IP network providing addresses for the equipment installed on site. The intra-station networks are then combined into a larger IP network that can be easily routed at the data centre. Therefore IP addressing schemes should be discussed and designed in close cooperation with the IT- or network department of the institution that hosts the central node before the installation campaign starts. It will be difficult to remotely change intra-station IP configurations again after the network installation has been completed. Another aspect to consider is that sensor networks usually change and grow over time, be it with additional equipment added at stations or additional stations added to the network. The developed IP schema should also address this and ensure the scalability of the system.

## 4 Overview of current communication technologies

### 4.1 Wired communication technologies

Wired solutions are usually cheap, robust, and provide sufficient throughput capabilities to transport seismic data. However, they have strong limitations regarding the distance to be covered (cable laying effort). Generally, they only provide a good solution for the intra-station network connecting the components on site. Most seismological instruments are already equipped with communication interfaces, such as Ethernet cards or serial ports. The following list also indicates serial and Ethernet based solutions, if the distance at a station exceeds the standard limits of these technologies.

The industry standard ANSI EIA defines different specifications of communication links based on serial ports.

EIA-232 or RS-232 (Texas Instruments, RS-232, <http://www.datasheetarchive.com/ANSI%2FTIA%2FEIA-232-F-datasheet.html>) is the classic serial connection. It provides data rates up to 19200 Baud using a null modem cable with a maximum length of 15 m. Longer transmission lines can be used but will decrease the data rate (e.g., 300 m, 4800 Baud).

Equipment, such as computers, digitizers, or communication terminals often provide integrated RS-232 interfaces already (Figure 2). Configuration of the link is straight forward and easy by configuring baud rate, data bits, parity, stop bits, and flow control on both sides of the link.

**Figure 2** Example of a serial connector and a serial PCI card.

If distances or data rate requirements are too high to use RS-232, another option is the use of EIA-485 (RS-485) cards (Texas Instruments, RS-485, <http://www.datasheetarchive.com/TIA-485-A-datasheet.html>). This specification provides a cable length of 1200 m and 12 Mbit/s throughput, however, this maximum transfer rate is achieved only with cable lengths up to 15 m.

If RS-232 interfaces are already integrated into the equipment and only the distance to be covered is too large, RS-232 to RS-485 adaptors provide a valuable alternative (Figure 3). However, this will not increase the data rate provided by RS-232.

**Figure 3** Example of an RS-232 to RS-485 adaptor.

The Institute of Electrical and Electronic Engineers (IEEE) developed the standard IEEE 802.3, which defines different specifications of Ethernet based communication links (IEEE Standards Association, 802.3, <http://standards.ieee.org/about/get/802/802.3.html>).

The most commonly used specification nowadays is Fast Ethernet (100Base-T) providing up to 100 Mbit/s transmission rate over shielded or unshielded twisted pair copper cable (STP/UTP). Equipment to be connected needs a network interface card (NIC), which is often already integrated (Figure 4). An Ethernet switch then connects the different devices into one local network. The maximum cable length (segment size) on 100Base-T should not exceed 100 m between two devices. For the installation of the RJ45 connectors a crimping tool is needed. Link configuration is easy by configuring IP number, netmask, and gateway IP.

**Figure 4** Example of an RJ45 connector and a PCI based network interface card.

A 100Base-FX PCI card can be added to the equipment if a PCI slot is available. If the equipment already has integrated 100Base-T interfaces, an external 100Base-FX transceiver can be used to convert from 100Base-T to 100Base-FX (Figure 5). 100Base-FX supports a 100 Mbit/s transmission rate over fiber optic cables with a maximum cable length of 2000 m. In addition to supporting longer distances, fiber optic cables are immune to electrical hazards, such as lightning strikes and ground currents that may occur.

**Figure 5** Example of an external 100Base-FX transceiver and SC-connectors.

The fiber optic connectors are commonly known as "SC" connectors. Only qualified personnel may install these connectors and a range of special tools are needed (Fiber Stripper, Cleaver, Wipes, Kevlar Scissors). It is also possible to purchase pre-fabricated cables and take them to the site.

Another possibility to extend FastEthernet beyond the normal IEEE 802.3 limitation of 100 m is the use of a pair of VDSL Ethernet Extenders (Figure 6). With increasing cable length, data rates will decrease from the 100 Mbit/s provided by 100Base-T, but cables between the terminals can be extended up to some kilometers by using normal STP, UTP or even common RJ11 telephone cable. A cable length of 8000 m will limit the data rate to 128 kbit/s.

**Figure 6** Example of a VDSL Ethernet Extender.

#### 4.2 Wireless communication technologies

Wireless solutions are usually cheap and easy to install. They can be used to link longer distances, more than 1000 m. They provide sufficient throughput capabilities to transport seismic data. However, they are relatively sensitive to obstacles in the wave propagation path and to changing atmospheric conditions that can attenuate the signal. A clear "line of sight" between transmitter and receiver is enough for a robust connection for very short links only. Longer distances are very prone to RF signal attenuation based on rain fade and Fresnel zone obstruction. They require a proper link budget calculation to ensure stability (see 7.3.3 and 8.9.3). Wireless modems/ routers have the disadvantage of increased power consumption compared to wired solutions. Systems usually consume between 5-10 W on each side of the link, which impose additional demands on the power system at the station.

The WLAN standards IEEE 802.11g (2.4 GHz) and IEEE 802.11a (5 GHz) support data transmission over a wireless terrestrial link (IEEE Standards Association, 802.11,

<http://standards.ieee.org/about/get/802/802.11.html>).

Due to its widespread use, the cost of 2.4 GHz equipment is generally lower, but the frequency band is also used by other wireless communication technologies, such as Bluetooth and microwave systems, which can lead to harmful interference in populated areas. Running a wireless LAN link involves no operational costs as frequencies can be used freely. WLAN can cover distances from 50 to 500 m using omnidirectional antennas. Using directional antennas, the coverage can be extended to several km (Figure 7). The performance of some devices, especially in combination with directional antennas and a free Fresnel zone, allows connections over very long distances. In tests, links over up to 70 km have been achieved by the use of directional antennas. The maximum allowed radiated power of WLAN systems (calculated from transmission power and antenna gain) is usually limited by national regulations and must not be exceeded.

**Figure 7** Examples of omnidirectional and directional antennas and a WLAN modem.

The data transfer rate on both specifications, 802.11a and 802.11g, is 54 Mbit/s, although these rates are seldom achieved in practice. With the latest specification 802.11n maximum data rates can be increased up to 600 Mbit/s by expanding the channel width from 20 MHz to 40 MHz and establishing several physical input and output channels using multiple separate antennas.

Generally, an increase in link distance will decrease the maximum data rate provided by the system. Especially for long range links, the installation can become quite complex with very high mast poles and difficult alignment procedures. Link distances can also be doubled with the use of “repeater stations”.

A number of commercial products support data transmission over radio frequency (RF) telemetry links. The systems mainly differ in transmission rates, operating frequencies (VHF 160-200 MHz and UHF at 450 MHz and 900 MHz) and modulation techniques. Running the system involves no operational costs as the frequencies can be used freely, however, some frequency bands need operating permissions by national agencies.

Bidirectional broadband systems can provide transmission rates of 150 kbit/s. Some systems specialize on link distance and provide up to 150 km coverage without repeaters (Figure 8). With increasing link distance, the transmission rate decreases for a given transmitter power. Especially for long range links, the installation can become complex with very high mast poles and difficult alignment. Link distances can be doubled with the use of “repeater stations”.

Compared to WLAN links, RF links are more robust against rain attenuation due to the lower frequencies used. However, terminals are generally more expensive.

If available, it is also possible to use the public mobile phone network for data transmission.

Packet oriented standards extending the Global System for Mobile Communications (GSM), such as GPRS, UMTS and LTE support both transmission of voice and transfer of data. Some available wireless modems have built-in ability to connect to all three services (Figure 9). Cell availability is depending on the provider and usually limited to inhabited areas.

Provided data rates differ depending on the standard

**Figure 8** Example of an RF telemetry modem and a Yagi antenna.

**Figure 9** Example of a mobile phone antenna and modem supporting all standards: GPRS, UMTS and TLE.

used (GPRS 53.6 kbit/s; 384 kbit/s; LTE 100 Mbit/s) but also on saturation of the shared infrastructure. Especially during and after catastrophic events, such as earthquakes, congestion or complete system blackouts are common. Configuration and installation of the modem is straight forward and easy. No antenna alignment is required.

### 4.3 Satellite communication technologies

At some remote stations satellite-based systems are the only alternative for seismic data transmission due to their availability at even very remote locations. Due to their independence from terrestrial infrastructure, they are very robust against failure during natural disasters. However, satellite capacities are generally shared with other companies/ services. Link saturation problems, which may occur, can be overcome by configuring bandwidth allocation methods such as committed information rates (VSAT) or constant bit rate modes (BGAN, Thuraya). Therefore, these systems provide a robust solution for early warning systems that require very high availability even during exceptional circumstances.

VSAT terminals represent the current state of the art measure for permanently installed seismic stations. Depending on their location, a suitable satellite (footprint, see Figure 10) and teleport operator must be selected. In principle, VSATs can be used worldwide, with the exception of the polar regions (latitudes larger than 70 degrees). Links can provide data rates up to several Mbit/s. Depending on data rate requirements of the station or the entire network, suitable bandwidth must be allocated.

**Figure 10** Example satellite footprint of Eutelsat 21B (source: [www.eutelsat.com](http://www.eutelsat.com)).

VSAT systems generally work on Ku-band, C-band, and Ka-band frequencies. C-band systems (smaller rain attenuation, larger antennas) are more common in Southeast Asia, Central and Southern Africa and Latin America, while Ku- and Ka-band systems (smaller antennas, but susceptible to rain attenuation) are more common in Europe, North Africa, Central Asia and North America. The influence of rain attenuation can also be mitigated by the use of adaptive coding and modulation techniques, e. g., utilized in DVB-S2. The required equipment consists of an indoor unit (modem) and an outdoor unit (Figure 11).

**Figure 11** Example of a VSAT modem (indoor unit) and parabolic antenna with receive and transmit unit (outdoor unit).

The outdoor unit (antenna, transmitter, and receiver) must be chosen depending on the calculated link budget. Transportation of antennas can cause problems, as typical sizes for Ku and Ka-band range between 75 cm and 1.8 m and C-band between 1.8 m and 2.4 m.

Another great disadvantage of a VSAT system is the high power consumption. Modems usually require around 25 W and additional 5-10 W per Watt of transmit unit power (BUC), which adds up to an overall consumption of approximately 35-70 W. Complex tests (cross-polarization and 1 dB compression test) must be performed, together with the satellite or teleport provider, during installation in order to activate the link. Compared to other satellite communication systems, the operational costs are low (see Table 3).

The Inmarsat BGAN satellite communication system uses three geostationary satellites, which provide global coverage up to 70 degrees latitude. The system does not cover the polar regions (Figure 12). It allows the transmission of data with a maximum upload rate of 240 kbit/s. Data volume-based tariffs (usually cheaper) or time-based tariffs (for real-time transfers) can be selected. Compared to VSAT, the transfer costs are very high in both modes. The system should be deactivated for times when no data transfer is taking place.

There are BGAN terminals of different manufacturers on the market. All of the devices are very compact, comparable to the size of a laptop, weighing less than 3 kg and have relatively low power consumption (less than 25 W). Modem and antenna are usually combined in one piece of transportable outdoor equipment (Figure 13). During installation, the terminal antenna must be roughly aligned to one of the three BGAN satellites (5 degrees accuracy sufficient). No complicated activation tests are required, however the SIM card must be commissioned/ activated by the BGAN provider before it can lock to the network.

**Figure 12** BGAN coverage map (source: [www.inmarsat.com](http://www.inmarsat.com)).

**Figure 13** Example BGAN modem with integrated antenna.

Thuraya provides a satellite telephone service based on two geostationary satellites covering Europe, Australia, the Middle East, Africa, Central and Southeast Asia (Figure 14). It sells two data transmission terminals: Thuraya IP and Thuraya IP Plus.

Both terminals can be used in two data transmission modes: “Standard IP” has a variable bit rate and offers up to 444 kbit/s data connectivity on a shared mode or best effort basis. “Streaming IP”, also known as Constant Bit Rate offers dedicated data connectivity ranging from 16 kbit/s to 384 kbit/s.

**Figure 14** Thuraya coverage map (source: [www.thuraya.com](http://www.thuraya.com)).

Modem and antenna are integrated in one piece of equipment weighing less than 2 kg (Figure 15). Power consumption of both terminals is less than 25 W while transmitting. Prices for terminals and transmission are comparable to Inmarsats BGAN system.

**Figure 15** Thuraya IP Plus modem with integrated antenna.

The Iridium satellite telephone system provides global coverage for all latitudes, including the poles. Since the 66 cross-linked low-Earth orbiting (LEO) satellites have polar orbits, the coverage above the poles is even particularly good (Figure 16). The antenna of the Iridium terminal need not be aligned with a satellite, hence installation is very simple.

**Figure 16** Iridium global coverage map (source: [www.iridium.com](http://www.iridium.com)).

Iridium offers different data services. The only broadband data transmission OpenPort provides data rates up to 128 kbit/s. The tariff plans of the OpenPort system are more complicated compared to BGAN, and transmission costs are generally higher. Both parts of the system (ADE (above decks equipment) – antenna and BDE (below decks equipment) – modem) are easy to install (Figure 17). No activation tests are required, however SIM cards must get commissioned/ activated by the provider. The power consumption in data transfer mode is less than 25 W.

**Figure 17** Iridium antenna (ADE) and OpenPort terminal (BDE).

Launching in 2015, Iridium NEXT will substantially enhance and extend Iridium services, delivering higher data speeds (L-Band: 1.5 Mbit/s, Ka-band: 8 Mbit/s) (Iridium, Iridium Next, <http://www.iridium.com/about/iridiumnext.aspx>).

## 5 Conclusions

All technologies discussed in the previous paragraph provide certain advantages and disadvantages, depending on the particular issues under consideration. It is important to quantify the differences and compare them to see if they really matter. Moreover, even there may be more than one suitable technology. It is obvious that choosing the right one can reduce the overall costs of the project.

Intra-station networks can be implemented using wires, based on the provided interfaces integrated in the seismic equipment (serial or Ethernet). Using adaptors, distances can be

easily extended up to several hundreds of meters, if needed. To avoid extensive cable laying work, wireless LANs can also be an alternative in unpopulated areas, where interferences are not expected.

**Table 3** Comparative matrix for communication systems used in seismic networks. For column Installation/ Activation, Easy/ Moderate/ Complex have been defined as follows: Easy - no expert knowledge required; Moderate - basic network knowledge sufficient; Complex specialist knowledge/or special tools needed. Numbers indicated in columns Hardware- and Operating Costs are estimations in \$US and should only be used for relative comparison.

Local inter-station networks can be set up using WLAN and directional antennas if stations are in less than 70 km range. Using RF links, distances can reach up to 150 km at most. Both systems are prone to interference with other wireless systems in urban areas and sound link budget calculations should be performed which require special knowledge and tools (e.g. a

spectrum analyser). The system distance limitations can be extended by the use of repeater stations, but this will add complexity to the communication network and complicate troubleshooting and maintenance.

In case mobile phone reception exists at the station and reliability during earthquakes is not of highest importance, mobile phone modems can be a low priced and very effective alternative.

For regional and global networks, satellite based communication systems are available even in the remotest areas, but come with a large price tag. For applications requiring high availability during global/ regional disasters, it is reasonable to rely on space-based infrastructures. VSAT systems have lower operational costs, but are difficult to transport, install, and activate. The high power consumption of VSATs increases the installation costs further. However, for permanent streaming from seismic stations with sampling rates higher than 10 Hz, VSATs are currently the only financially feasible selection as operational costs of the satellite-based alternatives are very high.

For temporary installations or very low sampling (data) rates Inmarsats BGAN or Thuraya are a good solution. These systems are easy to transport, install and activate. For the polar regions above the 70<sup>th</sup> latitude, Iridium provides the only satellite-based communication solution. These communication technologies may become a good alternative for permanent seismic networks in the future if prices will further decrease. Another way to allow the extensive usage of these technologies will be to complement existing seismic networks with stations running the pre-processing of waveform data on-site, if a computer is available. This would drastically reduce data transfer requirements of the inter-station network, because only a few parameters, such as picks, amplitudes, peak ground acceleration, velocity, etc. may be transmitted to the data centre and not the complete high sampling rate waveforms.

## Acknowledgments and comments

We thank P. Bormann for additional editing of this Information Sheet. We are also grateful to the reviewers C. Milkereit and K. Wendlandt, which improved the text significantly. P.L. Evans and S. Gensch kindly amended our English.

Identifying the name of the instruments' manufacturers is not meant to be an endorsement of their products. Prices and costs mentioned in this Information Sheet can vary a lot in time and depending on regions/ countries. They cannot be used as absolute values but only for relative comparison. The list of manufacturers provided in Appendix 2 is a subjective selection and is by no means complete.

## Appendix 1

### Example design of a communication infrastructure for a seismic network of 25 stations used for tsunami early warning in the Indian Ocean

#### Step 1) Requirement Analysis

Continuous seismic data streams are needed at the data centre to calculate earthquake parameters in real-time, identify if there is a tsunami potential and send out a timely warning to the population under threat.

- Stations must be constantly online, streaming data on permanent communication links to the data centre.

The network is permanently deployed and will continuously be enlarged.

- Operational and maintenance costs outweigh initial investments in equipment, training, transportation, installation and activation.

Each station hosts two types of sensors, a very broad band seismometer and an accelerometer, both having three components. Selected sampling frequencies are 50 Hz for the seismometer and 100 Hz for the accelerometer, both connected to a 24 bit digitizer.

- $3 \text{ components} * 50 \text{ Hz} * 24 \text{ bit} + 3 \text{ components} * 100 \text{ Hz} * 24 \text{ bit} = 10800 \text{ bit/s}$ .

The SeedLink protocol is used to transfer station data to the observatory. SeedLink uses Stein compression, which can almost halve the data quantity (see 8.6.6).

- The data to be transmitted using the communication system varies between 5-10 kbit/s per link depending on compression efficiency.

**Figure 18** Geographical distribution of the stations and observatory location.

The deployment area of the network is along the Sunda arc covering several thousand kilometres (Figure 18).

- Link distances between stations are generally over 500 km.

Stations are in very remote areas and located in three different countries. To reach stations, long and expensive journeys are necessary with several connecting flights.

- A secondary backup communication system would be useful to reduce maintenance costs.

High network availability is required, being specified as above 99 %. Data streaming must be ensured during and immediately after the occurrence of large earthquakes.

- Link robustness is of highest importance, higher than budget constraints.

Table 4 summarizes the requirements of the seismic network used for tsunami early warnings that are relevant for the communication system selection.

**Table 4** Similar to Table 1 but tailored for a tsunami early warning system.

| Application Type             | Geographic Spread                                 | Sampling/<br>Data Rates | Link Type                                  | Required Robustness | Remoteness of Stations |
|------------------------------|---------------------------------------------------|-------------------------|--------------------------------------------|---------------------|------------------------|
| Tsunami Early Warning System | Network:<br>>8000 km<br>Inter-station:<br>>500 km | 5-10 kbit/s per station | Continuous link for real-time data streams | Very high           | Very remote            |

### Step 2) General design considerations for the communication system of the seismic network

Requiring no data transfer between stations, but having a central data centre collecting all waveforms directly from remote sites, the “natural” topology in regards to the general data flow is a star topology (Figure 19). The analysis also showed that link reliability and real-time data availability are of high importance. The star topology increases robustness, as a single link outage can only affect one station. Compared to other topologies, it simplifies troubleshooting and maintenance as there are no multi-hop links to reach any of the stations.

**Figure 19** Network topology with link distances indicated in kilometres.

To simplify maintenance efforts, all stations are deployed with common hardware and common configurations. Data rate requirements are the same on each link with a maximum transmission rate of 10 kbit/s (assuming no compression). Depending on the compression efficiency, the data rate will vary over time and, under normal conditions, may be as low as 5-7 kbit/s. This leaves some spare bandwidth that can be used to transmit buffered data

collected during communication/ power outages as soon as the link is re-established. The acquisition protocol (SeedLink) is capable of filling gaps, acquiring old data, and continuing to acquire real-time data as soon as gaps are filled (see 8.6.4). As a general rule of thumb, 30% of the total link budget should be allocated for this purpose. This also allows connecting to a station for trouble shooting purposes without affecting the real-time streaming.

**Table 5** The implemented IP plan ensures scalability and simplifies maintenance in regards to troubleshooting and routing at the data centre.

| Inter-station network IP | Station                          | Intra-station network IP | Number of hosts at station |
|--------------------------|----------------------------------|--------------------------|----------------------------|
| 172.16.0.0/16            | Station 1                        | 172.16.1.0/24            | 254                        |
|                          | Station 2                        | 172.16.2.0/24            | 254                        |

Using the scheme shown in Table 5, a total of 255 stations are possible, each with up to 254 devices within the intra-station network. A private IP block was chosen, because equipment at the stations does not access the Internet and does not need to be reachable from there. Data is directly transferred from stations to the data centre and there it is shared with other national and international observatories using a central acquisition server reachable from outside.

### Step 3) Selection of the communication technology

According to Table 3, the geographical extent and large inter-station distances drive the selection of the suitable communication technology towards mobile phone networks or satellite-based solutions. Mobile phone networks are excluded because they cannot provide the required link reliability for a tsunami early warning system.

Out of the four satellite-based solutions introduced in paragraph 4.3, VSAT was chosen as the best candidate. Table 6 shows rough cost estimates, from which it is apparent that VSAT is considerably cheaper in the long term. The high operational costs of BGAN/ Thuraya/ Iridium outweigh the additional investments needed to install a VSAT terminal after just a few weeks.

**Table 6** Relative cost comparison for satellite-based communication systems. Initial investment cost estimation includes: price estimation for communication equipment and investment for independent power supply system (based on photovoltaic and batteries). Operational cost estimation is based on the assumption that a station produces approximately 100 MB data per day. VSAT contracts are usually priced in kbit/s with a minimum duration of one month.

| Estimated Costs per Station | VSAT      | BGAN and Thuraya | Iridium     |
|-----------------------------|-----------|------------------|-------------|
| Initial Investment:         | \$US 7000 | \$US 4000        | \$US 5000   |
| Operational Costs:          |           |                  |             |
| per week                    | \$US 200  | \$US 3500        | \$US 4900   |
| per month                   | \$US 200  | \$US 15000       | \$US 21000  |
| per year                    | \$US 2400 | \$US 180000      | \$US 250000 |

VSAT systems, when set up in star topology, have a dedicated station called hub that is the gateway for all stations. Additionally the hub has management and control functions, such as defining carrier frequencies, creating time plans and orchestrating the overall system by assigning transmit slots to each station. The VSAT hub is installed at the data centre, because qualified sat-com professionals are employed at the tsunami observatory.

Hub services can also be rented from teleport providers, which usually run VSAT hub services on different satellites at their teleport location. However, this will add an additional data link from the teleport to the observatory. Using the Internet to do so will add an unreliable link to the system, while a VSAT-based connection will double the required VSAT bandwidth and involved operational costs.

There are different manufacturers of VSAT platforms on the market that differ in protocols, modulation techniques used, and also in prices for the modems. Hub and stations must run with equipment of the same platform type (VSAT modem). Hub services rented via a teleport provider dictate therefore, which modem model needs to be purchased for a station.

All VSAT platforms can run on Ku-band, C-band, and Ka-band frequencies. The International Telecommunication Union (ITU) has categorized the region as a Region P, which designates regions with very high rain precipitation (ITU, Characteristics of precipitation for propagation modelling, [http://www.itu.int/dms\\_pubrec/itu-r/rec/p/R-REC-P.837-1-199408-S!!PDF-E.pdf](http://www.itu.int/dms_pubrec/itu-r/rec/p/R-REC-P.837-1-199408-S!!PDF-E.pdf)). Generally, rain attenuation increases with the frequency of the transmitted signal, making C-band the standard for reliable communication in tropic regions.

After the selection of the frequency band a suitable satellite must be chosen. This can be done by checking the coverage area of different satellites (Satellite footprint maps, <http://www.satbeams.com/footprints>). A so-called satellite footprint map shows coverage areas enclosed by contour lines indicating the level of EIRP (Effective Isotropic Radiated Power), a value representing the satellite signal strength in those areas. Figure 20 shows the footprint of the satellite selected for this case study. Based on the EIRP levels, link budget calculations done by qualified sat-com professionals will define dish size and transmit unit characteristics needed at each seismic station.

**Figure 20** The footprint of the Telkom 2 communication satellite covers the area of the seismic network.

#### Step 4) Implementation of the communication system

The intra-station network at all stations is based on Ethernet interfaces and a switch (Figure 21). The VSAT modem is configured to be the default gateway for all equipment on-site (intra-station network), so waveform data is transmitted using the VSAT network. In order to reduce maintenance costs, BGAN terminals are added at each station to provide a secondary

backup link. This link is only initiated for remote login and troubleshooting in case of a VSAT link failure.

**Figure 21** Intra-station network based on Ethernet using a switch.

The inter-station VSAT network is operated from the hub, which is located directly at the data centre. The BGAN network terminates at a ground station of the company offering the service. Using BGAN the traffic will pass the Internet before reaching the stations (Figure 22).

**Figure 22** Inter-station network and backup link.

The case study presented was implemented in the GITEWS project (GITEWS; <https://www.gitews.de>) as the backbone seismic network for the Indian Ocean Tsunami Early Warning System and is currently operational. For further information about the communication architecture and the selection and installation process, please refer to Angermann et al. 2010. The network is under continuous development and more seismic stations, as well as other sensors, are continuously added to the system.

## Appendix 2

## List of manufacturers and products

The following list of communication equipment manufacturers provides more details for further reading.

| Category                             | System       | Product                               | Manufacturer     | Web Link                                                                          |
|--------------------------------------|--------------|---------------------------------------|------------------|-----------------------------------------------------------------------------------|
| Wired communication technologies     | RS-232       | PCI cards                             | StarTech:        | <a href="http://www.startech.com/">http://www.startech.com/</a>                   |
|                                      | RS-485       | Cards and converter                   | SerialComm:      | <a href="http://www.serialcomm.com/">http://www.serialcomm.com/</a>               |

## Abstract

This information sheet gives an overview of some of the currently most popular and efficient tools for the retrieval of seismic waveform data from data centers. We do not attempt to provide a complete list of tools or exhaustive documentation. Instead it is our aim to provide some guidance and ideally whet the reader's appetite.

## 1 Overview

Digital recording methods have been used in seismology since about 1970. Digital methods have greatly increased data quality but they have also created new challenges. In order to allow efficient data exchange, the data had to be homogenized across different computer software and architectures. At the same time the exchange techniques had to keep pace with evolving new technologies. In particular, the advent of the Internet a little over 20 years ago and the continuously decreasing costs for network bandwidth have had great impacts on the way seismic data are acquired, archived, exchanged and processed today.

This chapter gives an overview of the techniques that are now (2014) “state of the art” for retrieving seismic waveform data from data archives. Data retrieval methods can be basically categorized into three groups:

- interactive, web-based solutions
- non-interactive techniques suitable for automated batch-type requests
- continuous, real-time data transfer

We will present some of the more popular solutions for each of these groups and discuss their individual merits and disadvantages.

### 1.1 Definition of the subject

We want to request seismic waveform data in order to display, analyze or otherwise use them. In general, the request of waveform data takes place at the beginning of a possibly long work flow, which is, of course, very application specific. Data requests nonetheless do very often follow a certain sequence of steps:

#### A. Discovery of

- seismic events based on hypocenter location, magnitude, type, etc.
- seismic stations based on sensor location (often within a specific epicentral distance range), instrument characteristics, etc.

- a combination of both in order to highlight a certain region, e.g., for tomographic studies
- B.** Selection of stations and channels based on what we found in step A. This selection process often combines event and station criteria.
- C.** Selection of time windows, often based on a combination of event and station locations
- D.** Formulation and submission of the request
- E.** Wait
- F.** Pick-up of the data
- G.** Data pre-processing (extraction, conversion, scaling, etc.)
- H.** Data processing - the actual data analysis, display, etc.

The subject of this information sheet is to provide some guidance to the novice user through steps A-F. Our aim is not to provide a comprehensive recipe, but to discuss concepts, weaknesses and strengths of various data request techniques. For more in-depth and technical documentation, the (potential) user is referred to external documents.

## 2 Relevant data formats used for data exchange

Chapter 10.3 gives a comprehensive overview about data formats commonly used in seismology, both for parametric and waveform data. In the following, we briefly summarize only those data formats, which are currently the most relevant for the data retrieval from seismic data archives.

### 2.1 SEED format

The SEED data format (SEED - Standard for the Exchange of Earthquake Data) was designed for use by the earthquake research community, primarily for the exchange between institutions of unprocessed raw waveform data. It's specification is part of the SEED manual (FDSN, 2012). Today, SEED is also the format that is most commonly provided to the end user by all major seismic data centers, including IRIS DMC, GEOFON, ORFEUS DC, GEOSCOPE and other data centers of the FDSN.

SEED is a binary format and while it is in fact quite complicated, there is de-facto standard software available for decoding and thus helping the end user to convert it to formats used by the most common data processing software packages. This conversion software (rdseed), available from IRIS and add the URL, allows the seismologist to conveniently decode SEED and encode the data into application specific formats like the SAC or AH formats.

A SEED volume consists of an arbitrary number of so-called “blockettes”. The format of these blockettes is described in the SEED manual. There are many different blockette types for raw waveform data as well as for metadata describing the raw data (e.g., station location,

channel gain to convert digital counts into units of ground motion, etc.). Raw waveform data and metadata may also be shipped separately, then normally referred to as miniSEED and dataless SEED, respectively.

## 2.2 MiniSEED format

The miniSEED format is the raw data part of the SEED format. It only consists of those blockette types that are used for storing information about the actual waveforms. That includes the encoded waveform data themselves, but also basic metadata like station code, channel code, start time of a data record and -optionally- timing quality. However, neither event nor instrument response information (not even a gain factor) is encoded in MiniSEED, because these metadata generally change very rarely if at all. They are therefore normally transmitted separately from the waveforms (often in the form of dataless SEED). This makes miniSEED a very efficient, light-weight format for archival as well as real-time exchange. MiniSEED consists of fixed-size blockettes as SEED. A miniSEED data blockette is also often referred to as a “record”. The physical size of a record, which is the smallest block containing contiguous data, is normally a multiple of 512 bytes. The most commonly used record sizes are 512 or 4096 bytes, but 512 bytes is presently the most common record size and is also used by data exchange protocols such as SeedLink described below. Generally the number of data samples that can be stored within one miniSEED record depends on the sampling frequency and efficiency of data compression, besides the physical record size. A 512-byte record can store approximately 400 samples of data if data compression is used, corresponding to data snippets of 20 seconds length at a sampling rate of 20 Hz. For 100-Hz data, the data snippets are accordingly shorter (approximately 4 seconds). This causes a latency of typically 20 seconds in acquiring 20-Hz data, which might be of concern for certain early-warning applications. Such applications, however, commonly record data at a higher sampling rate like 100 Hz, which already dramatically reduces the latency to less than 5 seconds. The processing can be further reduced if the data recorder sends out the data records prior to filling them with the maximum possible number of samples. Currently miniSEED is the basis for or is at least supported by all relevant real-time data processing and archival systems.

## 2.3 Dataless SEED format

While miniSEED contains only the raw waveforms (usually in digital counts) without any metadata, dataless SEED contains only metadata such as station location and instrument response without any waveform data. This separation allows storage, exchange and configuration of station inventories with the smallest possible overhead.

The main disadvantage of SEED is that it is not easily extensible. For instance the station identifier consists of up to five alphanumeric characters. This limitation is simply due to a pre-defined fixed space limit. There are many other limitations in SEED and the FDSN has therefore decided to introduce a new, XML (eXtensible Markup Language)-based format for station metadata. Dataless SEED will nevertheless continue to be of importance for the seismological research community for many years to come.

## 2.4 FDSN stationXML

Being an XML (eXtensible Markup Language) based format, FDSN Station XML was designed to overcome the limitations of dataless SEED, particularly the limited extensibility. The format has been approved by the FDSN in 2013 and is meant to become – in the long term -- a replacement of the dataless SEED format.

Some data centers and services make their station inventories available as FDSN StationXML already. Software exists for both the conversion to/from dataless SEED as well as for direct use as inventory data format.

## 2.5 Further information

For further information about the FDSN standard formats the reader is referred to

- the SEED format version 2.4 specification (FDSN 2012)
- the FDSN StationXML specification (FDSN 2013)

## 3 Access to archive data

20 years ago, the access to seismic data could be a lengthy and time-consuming procedure, especially for large data volumes. Requests had to be submitted to the data centers and data were returned, e.g., on magnetic cartridges or CD's. Due to the availability and greatly reduced costs of high-speed Internet connections, the data exchange through physical media is now obsolete (2014). The Internet can be and is nowadays used even for synchronization of large data archives. E.g., seismic noise studies utilize huge amounts of data that can now be transferred over the Internet. The cost of hard disk space has decreased greatly, with the benefit for data centers of being able to now store their entire archives online on hard disk, which has brought additional dramatic speed advantages.

This offers many new possibilities for data centers to offer their data in ways more convenient to the users than ever before. While it may have taken weeks to process data requests at the data center and to ship the data tapes to the user, it is now a matter of minutes or at worst hours between the arrival of the user request and the data shipment. Some request mechanisms are even fast enough to provide data "on the fly" within seconds. New approaches for data archival, like distributed data archives, have become possible.

Below we will describe interactive and non-interactive data access techniques.

### 3.1 Interactive methods

In this section we will explore several web pages that provide interactive access to seismic waveform data. At each of the data portals we will perform an example data request for broadband waveforms of the 2011 Tohoku earthquake. We are interested in teleseismic P waves and want to request all public broadband data from stations within 90 degrees epicentral distance. For the P waves we can restrict our request to the vertical component only. Due to the magnitude of the earthquake and long rupture duration, we request time

windows of 5 minutes before to 10 minutes after the predicted P-wave arrival time. Such a data set may be used, e.g., for magnitude computation or body-wave moment tensor inversion.

### 3.1.1 IRIS Wilber3

IRIS Wilber is a web application for requesting event-oriented data from the IRIS DMC. It allows users to easily find earthquakes from DMC's database and access waveform data based on a particular event. Waveform data are prepared using earthquake travel times and may be downloaded in a variety of data formats including SEED, SAC, and miniSEED. It is worth mentioning that WILBER3 interacts with information at the IRIS DMC totally through FDSN web services deployed at the IRIS DMC.

- URL: <http://www.iris.edu/wilber3> (see Figure 1)
- At *Load Event Data* select *Since 1990, M5.5+*
- At the right panel, *Date* field, enter **2011-03-11** as both start and end date
- You are now offered a list of events that occurred on the day 2011-03-11. Scroll to the bottom of the list and select the Tohoku main shock.
- Go to the *Select Stations* dialog (see Figure 2). A world map with available stations is now displayed, with the seismic travel times as isolines.
- Seismic Network). To select a different (virtual) network, click on the text field and select the network from the pop-up menu.
- On the bottom panel the selection can be fine-tuned on a per-station level if needed.
- Finally, hit *Request Data* to get a pop-up window in which you have to specify time windows and data format (see Figure 3). Most users will request either SEED or MiniSEED format, but options like SAC can be selected, too. In our example we select output as SEED volume. In this case, the request will be processed by the IRIS BREQ\_FAST, which means that once the request is ready (usually within a few minutes) the user is informed by email which SEED file to pick up at the IRIS FTP server.

On the panel to the right of the map, you can further limit the station selections according to distance and azimuth with respect to the event, but also channels (default is BH? - all broadband channels) and (virtual) networks (default is GSN - IRIS Global

**Figure 1** Selection of seismic events using the IRIS Wilber 3 interface

### 3.1.2 EIDA WebDC

The WebDC web interface is a portal to the seismic waveform data archives at GEOFON, including the European Integrated Data Archive (EIDA) data holdings. It allows to request

- seismological waveform data and
- station inventories (Dataless SEED, Inventory XML).

from different data centers across Europe participating in the EIDA initiative. In order to retrieve data for the Tohoku earthquake follow these steps:

- URL: <http://webdc.eu>
- We start our request session at the *Explore events* tab (see Figure 4)
- Select a catalog: GFZ is default, USGS and EMSC are other options. Alternatively, a user-supplied event list may be used and uploaded to the WebDC server. This is particularly useful to request data for events not covered by the above earthquake catalogs.
- As in the Wilber3 example above, we again select **2011-03-11** as start and end date. By limiting the magnitude to 7 and above, we restrict our search to the Tohoku main shock and two major aftershocks.
- Once the main shock is selected, we move on to the *Explore stations* tab (see Figure 5) and select the GEOFON network (GE) and streams by code *BH*, which means broadband streams. By hitting "Search" the station selection is displayed on the map as well as in a list at the bottom of the page, where stations can be (de)selected individually if desired.
- Finally, to submit the request, we move on to the *Submit request* tab, where we can choose between relative and absolute time windows (see Figure 6). Relative time windows are specified relative to a selectable wave type (P by default). The data formats that can be requested include SEED, MiniSEED as well as station metadata (dataless SEED). After specifying a valid email address the "submit" button is hit to submit the data request to WebDC.
- After submitting the request, the user will be notified about it being processed by a blinking "Download data" tab at the top of the page. By clicking on that tab, a list of the most recent data request of the user (identified by the email address) will be displayed, along with the processing status and -once the request is completed- one or several download links (see Figure 7). Note, however, that the data may have been split into several volumes as EIDA is an integrated data center with several nodes in Europe, each of which is responsible for its own data. This also means that the user downloads the data directly from the respective node.

Figure 6 Data request submission

**Figure 7** Finally, download the data as a SEED volume

### 3.1.3 Remarks

Both presented interactive request methods are similar in that they greatly facilitate the whole process of event selection, station discovery and retrieval. They are the methods of choice for the retrieval of a limited data set for one or few earthquakes, especially if it is unclear which stations shall be used. If large data sets need to be compiled, the interactive sessions may be too time consuming. Fully automated processing is not possible at all, at least not until the data have been downloaded. This is where the use of non-interactive methods is required, which we will look at next.

## 3.2 Non-interactive methods

Any user who wants to retrieve large quantities of data, like many stations for many events, will quickly realize that while interactive methods provide an excellent starting point for exploring data archives, often at the beginning of larger projects, they are normally too inefficient to use if hundreds or thousands of data sets need to be retrieved. This is where automated requests using non-interactive request methods come into play. Automated requests are also needed in automated seismic monitoring environments.

A variety of automatic request tools exist, some of which have been in existence for many years and are widely known and used, others are newer and reflect technical developments of the recent years.

Here we will provide an overview and a discussion about some of the more important request tools.

### 3.2.1 Email based methods

Being one of the earliest Internet communication protocols, email was quickly adopted as a means for requesting and transmitting seismic data. Several different techniques have been in use over the years, some of which are now obsolete but mentioned here for the sake of completeness:

#### **AutoDRM**

developed at the Swiss Seismological Service (SED) at ETH Zürich. AutoDRM was a purely email based request service in which both the request as well as the compiled data volume were transmitted as text messages through email in GSE format. AutoDRM pioneered seismological data access but is now obsolete due to the availability of much more efficient techniques. However, some data centers especially in Europe, continue to provide this service.

#### **BREQ\_FAST**

is another email based tool and was developed by IRIS. Data requests are sent in an email message to a data request manager, where they are processed. Upon completion, the data are delivered via a medium as specified in the request. Nowadays the FTP Internet protocol is the most common medium, but for large data volumes magnetic tapes might occasionally still be the preferred media type.

A BREQ\_FAST request message consists of a header, in which the user provides some personal information like name, postal and email address. The user can specify a preferred media type for the data delivery and a request label, under which the request can be tracked.

Following the header, the request message contains an arbitrary number of lines, each of which consists of a combination of station/network/channel codes and associated time windows to be extracted. Each of the textual fields may contain wild cards, e.g., for matching more than one channel code to get all available components of a sensor.

For more information about BREQ\_FAST, see  
[http://www.iris.edu/dms/nodes/dmc/manuals/breq\\_fast/](http://www.iris.edu/dms/nodes/dmc/manuals/breq_fast/)

A detailed example will be shown below.

#### **NetDC - Networked Data Center Protocol**

Like BREQ\_FAST, requests are email based, whereas data are delivered to the user via either the FTP Internet protocol or magnetic tapes (Exabyte). NetDC is in principle superior to BREQ\_FAST because it allows the user to submit a data request without knowing where the data are stored physically. It introduced the concept of "networked data centers", where requests are automatically routed to the data center responsible for the data.

When making the data request, the user can choose between either receiving data from individual data centers or receiving the data as a single merged product from the data center originally contacted. Either way a user interested in data will have to contact only one site when making a request, which is certainly a big advantage.

Due to the availability of more modern request techniques, NetDC is now considered obsolete. While it is still in use at a few data centers (e.g. GEOSCOPE) it has already been shut down at the IRIS DMC in 2013.

Out of these three most popular email based request techniques, nowadays only BREQ\_FAST continues to be of importance and is supported by GEOFON, IRIS and EIDA. We will therefore briefly explain the basics of a data request using BREQ\_FAST.

### Example BREQ\_FAST waveform data request

In the following example, we want to request a recording of the 2011 Tohoku earthquake recorded at the GEOFON station Wanagama, Indonesia, which has the station code UGM. The GEOFON network code is GE. We want to retrieve all three components in a time window starting 10 minutes before and ending one hour after the earthquake origin time, which is 2011-03-11 05:46:23 UTC.

```
.NAME Joe Seismologist
.INST GFZ Potsdam
.MAIL Telegrafenberg, Potsdam, Germany
.EMAIL joe.seismologist@seismology.org
.MEDIA: Electronic (FTP)
.LABEL Tohoku-UGM
.END
```

```
UGM GE 2011 03 11 05 36 23.0 2011 03 11 06 46 23.0 1 BH?
```

As data for this particular station are archived both at GEOFON and IRIS data centers, the request may be submitted to either the GEOFON/WebDC (email: [breq\\_fast@webdc.eu](mailto:breq_fast@webdc.eu)), the ORFEUS DC (email: [breq\\_fast@knmi.nl](mailto:breq_fast@knmi.nl)) or the IRIS DMC (email: [breq\\_fast@iris.washington.edu](mailto:breq_fast@iris.washington.edu)). In general, however, when using BREQ\_FAST for requesting data, it must be known beforehand which data center provides what data, because the BREQ\_FAST service itself provides no functionality for station discovery. This is often not a problem, especially if the same set of stations (or “virtual network”) is always used for a certain analysis and if the number of stations is small enough to be easily manageable using e.g. home grown station inventories like station lists. When BREQ\_FAST was developed more than 20 years ago, this was possible simply because the digital seismic networks consisted of much fewer stations than today.

But things have changed. What if there are many stations in our region of interest and we want to use just as many of them as possible? What if the station/network configuration changes nearly on a daily basis like in the case of the EarthScope network? It then becomes increasingly tedious and time consuming to keep a local station inventory up to date. Fortunately, there are now services that make this task easier. We will explore these in more detail below.

### 3.2.2 ArcLink

ArcLink is a data request protocol developed within EIDA especially to facilitate access to distributed, de-centralized data archives. High-quality, digital seismic waveform data are nowadays openly available from many institutions and data centers world-wide. Data are therefore physically stored in different places. This requires tools that facilitate the discovery and access to such distributed archives. In particular, data requests need to be routed from a client to often several server nodes. ArcLink can therefore be considered an enhancement of the now discontinued NetDC.

ArcLink uses its own protocol language between an ArcLink server and an ArcLink client program. ArcLink is also the architecture behind the EIDA WebDC data portal. It consists of dedicated server and client software. For data retrieval, a client software is needed. There are several options, with the most popular being

#### **arclink\_fetch**

is a stand-alone download client, which is distributed as part of the SeisComp software package (Hanka et al., 2010). It is invoked either from the command line prompt or from within shell scripts:

```
$ echo '2011, 3, 11, 5, 36, 23 2011, 3, 11, 6, 46, 23 GE UGM BHZ *' | \
arclink_fetch -u "joe@seismology.org" -o GE.UGM..BHZ.mseed
```

The resulting MiniSEED file GE.UGM..BHZ.mseed can then be saved and viewed by using any seismogram viewer or be further processed.

#### **obspy.arclink**

is a library of client functions that are invoked from programs written in the Python programming language. Example:

```
$ python
Python 2.7.3 (default, Feb 27 2014, 19:58:35)
[GCC 4.6.3] on linux2
Type "help", "copyright", "credits" or "license" for more information.
>>> from obspy import UTCDateTime
>>> from obspy.arclink.client import Client
>>> client = Client(user='joe@seismology.org')
>>> t = UTCDateTime("2011-03-11 05:46:23")
>>> st = client.getWaveform("GE", "UGM", "", "BHZ", t-600, t+3600)
>>> st.plot()
```

Instead of plotting the data, it is of course also possible to write them to a file:

```
>>> client.saveWaveform("GE.UGM..BHZ.mseed",
... "GE", "UGM", "", "BHZ",
... t-600, t+3600, format='MSEED')
```

This will save the raw MiniSEED data to a file GE.UGM..BHZ.mseed, which can then be processed. Also other formats commonly used by data analysis packages are supported (e.g., SAC, SEISAN, GSE etc.)

### SeisComP3

is software for seismological data archival, exchange and processing. It has built-in ArcLink client support. In fact, ArcLink is the default archive access protocol of SeisComP (Hanka et al., 2010).

NOTE: ArcLink is a popular protocol in Europe within the EIDA initiative and within the SeisComP ecosystem. It is not supported by major data centers like IRIS DMC, however, and has therefore not become a world-wide standard. A standard archive access mechanism is provided by web services.

### 3.2.3 Web Services

Web services in general are a method of communications over the World Wide Web, hence the name. The fact that web services use the HTTP Internet protocol allows access to resources offered by web services usually even in tightly security controlled environments (e.g., behind network firewalls, etc.), because the Internet ports used by the web services are the same as for interactively browsing the WWW. Many Internet technologies nowadays are based on web services and as a natural consequence web services also have been adopted in seismology as a means for exchange of waveform and parametric data.

Web services for seismic waveform data retrieval have been developed over the last approximately 10 years in several institutions in Europe and the United States, resulting in initially different and incompatible solutions. Fortunately in 2013, an agreement on a common web service standard could be achieved by the members of the FDSN. The set of web services defined in this standard are referred to as “FDSN web services” (FDSN, 2013):

**fdsnws-station** - For access to station metadata in FDSN Station XML format

**fdsnws-dataselect** - For access to time series data in MiniSEED format

**fdsnws-event** - For access to event parameters in QuakeML format

The access to the FDSN web services is very simple and there exists a variety of techniques to choose from. In fact, the HTTP protocol allows the use of any web browser to access data from an FDSN web service, which is very convenient especially for the novice user to explore the web service features. Non-interactive HTTP client programs like “wget” and “curl” may easily be used as FDSN web service clients. In addition, specialized client software exists to make the data retrieval simple and transparent.

The data request can be specified in two different ways. One is simply via a URL, which essentially must consist of the stream to load (possibly containing wild cards matching several streams at once) and the time window. The stream is specified by the network, station, location and channel codes. See the SEED manual for more details about these fields.

For example, if we want to request the same data as in the above example BREQ\_FAST waveform data request (70 minutes of data for the 2011 Tohoku earthquake recorded at GEOFON station UGM), the URL to fetch these data would be <http://geofon.gfz-potsdam.de/fdsnws/dataselect/1/query?sta=UGM&net=GE&start=2011-03-11T05:36:23.0&end=2011-03-11T06:46:23.0>

[11T06:46:23.0&cha=BH?](http://11T06:46:23.0&cha=BH?) This URL may simply be entered in any web browser and the resulting data file may be immediately viewed or processed.

Using the same URL, the data can also be fetched with command line utilities like “wget” or “curl”, which allows partial automation of data requests, e.g. using shell scripts. Since the URLs are very easy to generate, this is a very convenient method for requesting and immediately retrieving seismic data.

When many different stations or time windows shall be retrieved at one time, these cannot all be specified on a single URL. Here an alternative flavor of the web service comes into play, which uses the HTTP-POST technique to upload a request file to the web service. This request file contains lines with individual combinations of streams and time windows, thus similar to the BREQ\_FAST email requests. The text file containing the request is uploaded to the web service and the data are retrieved immediately.

NOTE that the data retrieved using FDSN web services are formatted as MiniSEED, which means that unlike full SEED volumes, they lack metadata such as instrument responses which, if needed, have to be requested separately using the fdsnws-station web service.

#### **wget**

is a general-purpose HTTP client that can also be used to request seismic data using the FDSN web services. Invocation simply as

```
$ wget -O data.mseed "http://..."
```

#### **curl**

is an alternative to “wget”. Invocation equally simple as

```
$ curl -o data.mseed "http://..."
```

#### **obspy.fdsn**

is a client library that may be used from programs written in the Python programming language. Example:

```
$ python
Python 2.7.3 (default, Feb 27 2014, 19:58:35)
[GCC 4.6.3] on linux2
Type "help", "copyright", "credits" or "license" for more information.
>>> from obspy import UTCDateTime
>>> from obspy.fdsn import Client
>>> client = Client("GFZ")
>>> t = UTCDateTime("2011-03-11 05:46:23")
>>> st = client.get_waveforms("GE", "UGM", "", "BHZ",
... t-600, t+3600)
>>> st.plot()
```

Note the great similarity with the obspy.arlink example provided above. Instead of plotting the data, it is of course also possible to write them to file:

```
>>> client.get_waveforms("GE", "UGM", "", "BHZ", t-600, t+3600,
... filename="GE.UGM..BHZ.mseed")
```

This will save the raw MiniSEED data to a file GE.UGM..BHZ.mseed, which can then be processed. Note that unlike in the above obspy.arclink example, the data format is not specified because here the only available format is MiniSEED, as it is not possible to download full SEED using the FDSN web services. Note that the above call only retrieves raw waveform data. In order to retrieve metadata, the above ObsPy client provides a “get\_stations” method. Please refer to the ObsPy documentation for more details (e.g., Beyreuther et al. 2010, and the [ObsPy home page](#)).

### IRIS Fetch scripts

can be used on the command line or from shell scripts. Invocation example:

```
$ FetchData -N GE -S UGM -C BHZ -s 2011-03-11T05:36:23 ¥  
-e 2011-03-11T06:46:23 -o UGM.mseed -m UGM.metadata
```

In the above call both raw waveform data as well as basic metadata like sensor coordinates and gain are downloaded.

Data for GEOFON station UGM happens to be available from both GEOFON and IRIS. By default, the FetchData script connects to the IRIS fdsnws server. In order to connect to the GEOFON fdsnws server, this default can be overridden using so-called environment variables. The above call then becomes:

```
$ export SERVICEBASE=http://geofon.gfz-potsdam.de  
$ FetchData -N GE -S UGM -C BHZ -s 2011-03-11T05:36:23 ¥  
-e 2011-03-11T06:46:23 -o UGM.mseed -m UGM.metadata
```

### SeisComP3

comes with a fdsnws server implementation included, which can be configured to access the data through ArcLink or directly from a mounted file system. Additionally, SeisComP has built-in support for fdsnws-datasetselect as client. All SeisComP programs, which use waveform data as fixed time windows can be configured to retrieve waveforms through fdsnws-datasetselect.

### Other web service clients

for MatLab and Java are available for download under <http://service.iris.edu/clients>

As the number of data centers supporting FDSN web services increases, it should be possible to develop clients that can discover data holdings across the entire system of centers. For instance, IRIS is currently developing a web service that will look at the holdings of all data centers running FDSN web services, and return information to a client application that will enable parallel recovery of waveforms from multiple data centers. Again the data will be sent from multiple data centers directly to the client application allowing each data center to understand its customer base. A similar “routing” facility is also being developed in Europe within EIDA. Any such solution will require special “smart client” software to make this data center integration transparent to the user.

### 3.2.4 Data discovery

In the previous section about web services, we have assumed that the user knows which data streams to request. In general, however, this may not always be the case and we may want to make a selection of stations/streams based on ad-hoc criteria such as a geographical region or epicentral distance range around an earthquake. This “discovery” process becomes actually quite simple using the “fdsnws-station” web service. If for instance we want to request data from IRIS for all stations within 50 degrees around the 2011 Tohoku earthquake. Given the epicenter coordinates and the time window it is very simple to request a list of stations within that distance range:

[http://service.iris.edu/fdsnws/station/1/query?level=channel&format=text&channel=BHZ&network=I\\*&include\\_restricted=false&start=2011-03-11&end=2011-03-11&longitude=142.5&latitude=38.2&maxradius=50](http://service.iris.edu/fdsnws/station/1/query?level=channel&format=text&channel=BHZ&network=I*&include_restricted=false&start=2011-03-11&end=2011-03-11&longitude=142.5&latitude=38.2&maxradius=50)

This is a long URL, but the format is actually quite simple and almost self-explanatory. `level=channel&format=text&channel=BHZ` requests a text list containing BHZ channels. Stations without BHZ channels will therefore not be listed, allowing a crude pre-selection of broadband sensors. Here we want to list only stations from the IRIS networks (II,IU,IC).

The full specification for the FDSN web services can be found under <http://www.fdsn.org/webservices/>.

### 3.2.5 Outlook

Nowadays automated data retrieval is possible using email based techniques as BREQ\_FAST, ArcLink and web services. All of these techniques have their specific advantages and will continue to be available for years to come. BREQ\_FAST and ArcLink allow data retrieval as full SEED volumes, which the web services don't. Instead, the web services promote a stronger separation of waveforms (MiniSEED format) and metadata (FDSN StationXML). This may appear like a disadvantage and for many users used to working with full SEED it currently is. Work flows need to be adopted, which is not always trivial. However, the data separation also has advantages. Erroneous metadata may more easily be corrected if the metadata are loaded “on the fly” during processing. Use of XML as metadata format will allow extensions to the metadata schema more easily.

It is likely that in the future the web services become by far the most important request mechanism, as they rely not only on standard data formats but are also based on standardized protocols. The web services are therefore being adopted and implemented worldwide at a growing number of institutions. What the web services are currently lacking is a possibility for routing requests as in ArcLink. It is therefore still necessary to know where the data are physically located. Also it is not yet possible to request data depending on quality metrics. But at the time of this writing, there are several initiatives working in that direction and working solutions will likely become available within the year 2015.

## 4 Conclusions

We have presented some of the main methods for requesting seismic data. The interactive web portals provide an excellent way to conveniently and quickly retrieve the data for a

limited data set in a nearly self-explanatory way. If you have done it once you know how it works. Very little learning is required.

The non-interactive methods - web services or `arclink_fetch` but also old-fashioned email - are much more powerful whenever the requests can be automated, e.g. if very large and/or numerous data sets have to be assembled. Embedding these mechanisms into a work flow may require a little more work at the beginning. Client software like ObsPy helps to minimize the work, which will anyway soon pay off due to the greatly reduced work to retrieve the data.

## Acknowledgment

The very careful and constructive reviews by W. Hanka, T. Ahern and J. Wassermann are acknowledged with thanks, as well as the reviews and discussions at several stages of the developing draft with the Manual editor, who also cared for the final formatting.

## 1 How earthquake monitoring is organized in the United States

Earthquake monitoring in the US is organized under the Advanced National Seismic System (ANSS), a program operated by the US Geological Survey. The mission of the ANSS is to provide timely and accurate earthquake information products, including rapid estimates of their effects on the built environment across the Nation. The United States is divided into eight ANSS regions to facilitate monitoring on a regional scale and to foster partnerships with local universities and other seismic network operators. The California Integrated Seismic Network (CISN) is the umbrella organization for earthquake monitoring in the California region of ANSS (Figure 1).

**Figure 1** Schematic organizational diagram illustrating how the ANSS, and as an example the CISN and other regional networks (RSNs, numbered 1 through n) form a system. **Bottom left:** The main components of the CISN; **Bottom right:** Summary diagram to indicate the other seven regions of ANSS; BDSN – Berkeley Digital Seismic Network; CISN – California Integrated Seismic Network; CSMIP – California Strong Motion Instrumentation Program; NCSN – Northern California Seismic Network; NEIC – USGS National Earthquake Information Center; and SCSN – Southern California Seismic Network.

## 2 California Integrated Seismic Network (CISN)

There are more than 15 seismic network operators in California that share data real-time as part of CISN operations. The CISN consists of three management centers. First, the California Geological Survey (CGS) operates the California Strong Motion Program, and provides near real-time strong motion data and associated products from all CISN partners to earthquake engineers. Second, the Northern California Seismic Network (NCSN) in Menlo Park and the Berkeley Digital Seismic Network (BDSN) at UC Berkeley provide real-time reporting for northern California. Third, the Caltech/USGS Southern California Seismic Network (SCSN) provides real-time reporting for southern California. The CISN partners also contribute data to the USGS/NEIC, develop standards, and carry out joint development and implementation of new technologies.

Extensive real-time data sharing takes place within the CISN. Subsets of real-time waveforms are shared automatically for processing by partner networks between central processing sites. In addition, about 12 broadband and strong motion stations operated by the SCSN transmit data real-time to both the SCSN in Pasadena and the BDSN in northern California, and comparable 12 BDSN stations are also recorded in Pasadena for backup purposes. Also, several strong motion stations provide simultaneous real-time data feeds to the SCSN Pasadena and the CGS in Sacramento (Figure 2).

Amplitudes are produced at all three CISN processing centers and shared automatically to facilitate seamless production of ShakeMap. Most recently, proxy wave-servers are used in post-processing to access waveforms in remote data archives, and improve earthquake locations and magnitudes. All products are transmitted via the USGS operated middleware Earthquake Information Distribution System (EIDS) for publishing on the USGS/ANSS web pages. To ensure high availability of earthquake information following major earthquakes, the USGS contracts with a commercial Internet provider to host the ANSS/USGS web pages.

The CISN partners have developed and operate the ANSS Quake Monitoring Software (AQMS) for their earthquake monitoring needs. In 2009, the ANSS began deploying the AQMS software at five other major ANSS data processing centers across the US. The AQMS software is based on the Oracle database, Earthworm modules, a variety of CISN developed software modules, and open source IT software modules for state of health monitoring. A CISN working group curates the Oracle CISN schemas to maintain standardization. The AQMS software includes data acquisition modules, broadcast and capture modules, data analyst and duty-seismologist review modules, and modules for various processing threads such as generation of earthquake locations, magnitudes, moment tensors, and alarming functionality. The AQMS software also has various facilities for data archiving. Recent additions to the software include incorporation of QuakeXML and StationXML to facilitate catalog data and station metadata exchange.

Today the USGS National Earthquake Information Center (NEIC) is the backup for the CISN. The CISN partners share waveforms from selected seismic stations, as well as parametric products such as arrival time picks, hypocenters, and magnitudes in real-time with NEIC. If the CISN does not report within several minutes on an earthquake that just occurred, the NEIC will release available information to ensure timely and accurate reporting. Once CISN has recovered from a failure or significant new information is available, it may update the information previously posted to the USGS hosted and other web sites.

### 3 Southern California Seismic Network (SCSN)

The authoritative earthquake-monitoring region of the Southern California Seismic Network (SCSN) extends across southern California, from the US-Mexico international border to Coalinga and Owens Valley in central California. The SCSN also reports on earthquakes in northern Baja California, Mexico because these could possibly cause damage in the United

States. The region is home to almost 20 million inhabitants, including two of the ten largest cities in the United States (Los Angeles and San Diego) and the two largest harbors (Los Angeles and Long Beach) in the Nation. Emergency managers use SCSN information to coordinate rescue operations, guide inspectors in the search for damage, and to facilitate disaster recovery. The media broadcasts the earthquake information to satisfy public need for information.

The SCSN processes and records real-time data from about 425 seismic stations (station map shown in Chapter 8.7). It operates about 300 seismic stations and receives real-time waveform data from an additional 125 stations operated by partner networks. The SCSN seismic stations can be divided into three groups. First, the most modern group of 167 SCSN stations consist of broadband sensors, strong motion sensors, and high resolution dataloggers for digitization and data communications. The data from these stations are used for real-time determination of earthquake locations, magnitudes, moment tensors, and amplitudes for ShakeMap. The second group consists of about 35 stations that are equipped with only strong motion sensors and a datalogger. These stations provide amplitudes for ShakeMap and occasional arrival-time picks. The third group consists of 125 short-period stations that use legacy analog, frequency-modulated (FM) audible tone technology and Earthworm digitizers for data acquisition. These stations are low-cost and can be installed at seismically quiet sites with minimal security. The waveform data can be transmitted for long distances using analog FM radio with very low bandwidth. Although, the amplitude data have limited dynamic range and are often only calibrated using nominal response values, these stations provide arrival-time picks for improved location and depth determination as well as coda duration for determining magnitudes of small earthquakes. Eight Earthworm hubs that are spread across southern California aggregate the SCSN short-period stations and transmit digital waveform data to the central site in Pasadena.

We use SeisNetWatch, initially developed by Caltech and later adopted by ANSS, to track the state of health of the stations. Various tools are used to check delivery and the presence of current waveform data within the processing systems. The tracking of mass centering and issuing of recentering commands is semi-automated. In addition, firmware upgrades on dataloggers are done remotely using command and control tools.

The data flow path from the remote seismic stations includes the on-site equipment, the data communications path, and a data acquisition computer at the central recording site. The last mile data communications to each site may use copper wire, spread-spectrum radios, or optical fiber. The main long-haul data communications include digital phone lines (frame relay or T1 lines) and digital microwave circuits. The waveform data are acquired by front-end processors that broadcast the data on a private local network. Many computers that are connected to this network capture and process the waveforms or capture the data for archiving. For instance, a processing thread of Earthworm modules carries out the real-time picking of arrival-times, association, and hypocenter determination. A different thread harvests amplitudes and determines local magnitudes. Similarly, an earthquake-early-warning processing thread captures the waveform data to facilitate testing of algorithms for ultra rapid determination of source parameters.

The AQMS software provides various buffers to allow for intermittent failure or maintenance of the acquisition and processing system. The dataloggers at broadband and strong motion stations can store several months worth of waveform data on site. In addition, each import server has some amount of waveform data storage as a backup feature. At the central

recording site in Pasadena, wavepools that are populated with waveform data in real-time provide redundant storage for up to four months. These wavepools are accessed by many processes including the processes that perform final data archiving.

The Southern California Earthquake Data Center (SCEDC) archives all the SCSN data and distributes the products of the SCSN. The waveform archiving is done within minutes of the occurrence of the earthquake using a system of request cards. The data center issues request cards for both event triggered waveforms where each request card specifies a time window of waveform data for a selected station channel of data. It also issues request cards for six hour windows of continuous data to the wavepool that is operated as part of the real-time systems. All parametric data determined by the real-time systems are stored in the database. During post-processing, data analysts use tools to display the waveforms, modify or add arrival time picks or amplitudes. They can also relocate the earthquake and update the magnitude. All of these actions result in updates in the database for that particular event. As the SCSN processes the data for detected earthquakes, outside researchers can also access all the data in the database, within minutes or as soon as the data are entered into the archive.

The SCSN products include the southern California earthquake catalog, event gathers (triggers) of waveforms for nearly all events back to 1981 and for some events extending back to 1976, continuous broadband waveforms from 1999 to present, continuous instrumental record of earthquake occurrence in southern California that includes four earthquakes of  $M > 7$  extends back to 1932. The SCSN and the SCEDC have maintained and published a catalog of earthquakes with magnitude of completeness above magnitude 3.25 since 1932 and above magnitude 1.8 since 1980 with consistent magnitudes over the whole time (Hutton, *et al.* 2010). The catalog is used to produce societally useful products such as USGS earthquake hazards maps as well as by seismologists for research.

Subsets of SCSN waveforms are also archived at the IRIS/DMC. In the 1990s Caltech started collecting broadband data using a new seismic network called TERRAscope (network code: TS). These data were at first only archived at the IRIS/DMC. In the late 1990s TERRAscope was merged with the SCSN under the network code CI. In 2004 the SCSN began data sharing with Earthscope/USArray and those data are also archived at the IRIS/DMC. At present, continuous waveform data from a subset of about 65 SCSN broadband and strong motion stations are being archived at the IRIS/DMC.

## 1 Introduction

When an earthquake draws public and media attention, the slightest differences in published epicentral location or magnitude can lead to basic questions such as “Who is right?” As a scientist, the seismologist answers as best he can what are the uncertainties and what are their causes. And invariably the same questions come back: “OK, but who is right? Was the earthquake located 2 km or 5 km to the north of the city?”

This example – which is common for felt events affecting border regions – illustrates how the differences in earthquake parameters are often taken by journalists and citizens as proof that at least one of the publishing organisations must be wrong, thereby raising doubt in the trustworthiness of the seismological community as a whole! Improving the accuracy of earthquake parameters will not solve the problem as small differences will always persist. In essence, this is a public communications issue rather than a scientific problem. To address this issue, a scheme must be defined that specifies the conditions under which an earthquake location determined by a given agency should be considered “authoritative” and should be used as it is by other agencies.

This article describes past efforts to address this issue and the authoritative location scheme approved by the members of the European-Mediterranean Seismological Centre (EMSC) and applied in EMSC real time information services ([www.emsc-csem.org](http://www.emsc-csem.org)) since November 2010. Not considered are the location procedures itself, the model assumptions on which they are based and their inherent errors. They are discussed in detail in IS 11.1.

## 2 Previous authoritative location schemes

Past efforts to define an authoritative location scheme at the EMSC and at other agencies were based on static geographical areas defined from the geographical extents of the seismic networks. A location is generally considered to be reliable when the azimuthal gap of the reporting stations is small. By definition, locations that fall within the bounds of reporting networks exhibit good azimuthal coverage. Therefore, these areas based on the network extents were supposed to identify the source for the *best* locations. Furthermore, this strategy implicitly recognises that local institutes are generally in the best position to accurately locate local earthquakes thanks to their knowledge of the local conditions.

This scheme properly addresses the majority of earthquake locations. However, it proved problematic in several cases. For example, it does not define which network should prevail in areas monitored by several networks. Such an overlap is not restricted to border regions: there

are also a number of European countries in which several seismic networks are in operation. Choosing *the* authoritative network for such regions is touchy and may become a political issue: how to prevent any national institute from claiming to be authoritative over its entire national territory even when part of that territory is poorly covered by its network?

In the end, these difficulties result from the fact that the underlying assumptions – that location accuracies are uniform within network boundaries and constant over long periods of time – are not always satisfied. Location accuracies depend on both the network geometry and on the relative spatial distribution and number of stations used in the calculation of the earthquake location.

The proposed authoritative scheme described below is based on the quality of the geographical coverage of the stations which actually report the considered event. It takes into account the actual operating status of each individual station at the time of the earthquake's occurrence, and only considers those stations that reported the event and were used in the calculation of the location.

### **3 An operational authoritative location scheme**

#### **3.1 Assumptions**

The simple and basic assumption of the proposed scheme is that locations which are both reliable and accurate must be considered to be authoritative and must therefore be published without modification for public consumption. Relocations should be restricted only to cases where a significant quality improvement can be expected. In essence, defining an authoritative location scheme amounts to the definition of the criteria for what can be considered a reliable and accurate location.

In the discussion below, we only consider the epicentral location. It is assumed that if the epicentral location is accurate and reliable, the focal depth is well constrained. Theoretically, this may not always be the case. In practice however, as we will see later, accurate and reliable locations are generally produced by local institutes which are in the best position to provide reliable depth estimates. Furthermore, as focal depth is often ignored by the public, it is a less critical element of a public communication scheme than the epicentral location or magnitude.

#### **3.2 Criteria for accurate locations**

Locations are considered to be accurate if they satisfy either of the 2 sets of criteria defined by Engdahl et al. (2001), or Bondár and McLaughlin (2009). Both criteria characterize the geometry and azimuthal distribution of the reporting stations at short distances (250 km), and were both derived from the study of explosions. The considered criteria are referred to as GT5 (for Ground Truth). If satisfied, the epicentral location is expected to be within 5 km of the actual epicentre, within a formal confidence level. For more details on the GT concept, global project and GT data base at the International Seismological Centre see section 7 in IS 11.1.

Table 1 and 2 present the GT5 criteria as defined by Engdahl et al. (2001) at a 90% confidence level and by Bondár and McLaughlin (2009) at a 95% confidence level, respectively, hereinafter referred to as GTA and GTB. The GTB criteria are more restrictive

than those of the GTA, but at the same time they select events not identified previously. Allowing the choice of either of the two sets of criteria maximizes the number of potential authoritative locations. Table 2 and Figure 1 present the alternative criteria defined by Bondár and McLaughlin (2009)

**Table 1** GT5 criteria at 90% confidence level for local networks, as defined by Engdahl et al. (2001).

|                                                                         |
|-------------------------------------------------------------------------|
| At least 10 stations at epicentral distance $\leq 250$ km               |
| At least one station at epicentral distance $\leq 30$ km                |
| Azimuthal gap defined with stations closer than 250 km $\leq 110^\circ$ |

**Table 2** GT5 criteria at 95% confidence level for local networks, as defined by Bondár and McLaughlin (2009). The secondary gap is the largest azimuthal gap filled by a single station. The criterion on the secondary gap implies a minimum of 5 stations. The definition of the network quality metric,  $\Delta U$ , is given in Figure 1.

|                                                                                   |
|-----------------------------------------------------------------------------------|
| At least one station at epicentral distance $\leq 10$ km                          |
| $\Delta U \leq 0.35$ when considering stations closer than 150 km                 |
| Secondary azimuthal gap defined with stations closer than 150 km $\leq 160^\circ$ |

$$\Delta U = \frac{4 \sum |esaz_i - (unif_i + b)|}{360N}, \quad 0 \leq \Delta U \leq 1;$$

$$unif_i = \frac{360i}{N}; \quad b = \overline{esaz} - \overline{unif}$$

**Figure 1** Definition of the network quality metric,  $\Delta U$ . If the stations, ordered by event-to-station azimuth were distributed uniformly they would align along a straight diagonal line and  $\Delta U$  would be zero. The dots in the right-hand panel represent the actual geometry of the network as plotted in the left-hand panel. The network quality metric is defined as the normalised area between the best fitting uniformly-spaced network and the actual network, shown shaded by grey lines in this example. The lower the  $\Delta U$  value, the more uniform the network geometry. Copy of Figure 5 in Bondár and McLaughlin (2009, p. 468), with © granted by the Seismological Society of America.

The constraint on the closest station, within 30 km for GTA and 10 km for GTB, strongly restricts the geographical area where authoritative locations could potentially be found for a given network (Figure 2). In practice, less than 5% of the locations collected in real time by the EMSC satisfy these criteria.

**Figure 2** Geographical area where GTA or GTB criteria are satisfied when considering all the seismic stations which contribute to the EMSC real time earthquake information services. Effectively, there cannot be any GTA or GTB locations in regions where inter-station distance is greater than 30 km.

The constraint on the closest station improves the confidence in depth for crustal events, but has no significant effect on epicentral location accuracy (e.g., Bondár et al., 2004). Therefore, in agreement with our basic assumption that our authoritative scheme is based on epicentral location only, this constraint is dropped for the purposes of defining what may be considered an accurate epicentral location. It doubles to about 10% the number of locations provided in real time which are potentially authoritative. More importantly, it greatly enlarges the geographical regions where such authoritative locations could potentially be found (Figure 3).

**Figure 3** Geographical area where authoritative locations could potentially be found for the EMSC real time services after relaxing the closest station constraint. This result is based on the assumption that earthquakes are reported by all the stations contributing to the EMSC real time services and located within 250km of distance.

### 3.3 Criteria for reliable locations

As for any measurement, a location is considered to be reliable if it can be independently and consistently reproduced within its inherent uncertainties. The estimation of location uncertainties is a complex issue (e.g., Thurber and Engdahl, 2000). By taking as reference locations the final solutions produced by the local networks and published in their final bulletins, Mazet-Roux et al. (2010) show that on average the locations produced in real time by the EMSC are within 10 to 12 km of the reference locations. The location procedures currently in place at the EMSC (velocity model and algorithm) are therefore very unlikely to produce a mislocation greater than 15 km when using the same dataset. We therefore set the criterion for a reliable location as being reproducible to within less than 15 km; larger differences are assumed to indicate an unreliable location.

The vast majority (98%) of the accurate locations (per definition in section 3.2) are also effectively reproduced to within less than 15 km, and can therefore also be labelled as reliable (Figure 4). However, there are still cases in which the differences in location are significant. Potential causes for these discrepancies were investigated. In some cases, the differences in

location were caused by data format or station code errors resulting in incorrect data inputs. However, in several cases no clear cause was identified. It was noted, however, that several of the submitted locations did not appear in the final bulletin of the reporting institute, or the locations in the bulletin were more than 15 km from the initially reported locations. These examples reinforce the importance of independent evaluation of location accuracy and reliability to avoid the publication of incorrect locations, even if the actual causes remain unidentified.

**Figure 4** Distribution of the difference in epicentral location between the accurate locations (per definition in section 3.2) provided to the EMSC and EMSC relocations using the same dataset. Results obtained from the 5,265 accurate locations provided to the EMSC in real time between Sept. 2008 and Sept. 2009.

### 3.4 Discussion

The authoritative location scheme presented in this work defines the conditions under which a real time epicentral location provided by one of the contributing agencies to the EMSC will be published without any modification in the EMSC public real time services. It does not intend to identify the best location, nor does it address any scientific issue. The intent is to avoid possible communication difficulties with the media and the public caused by differences in published earthquake locations, even if the differences are scientifically and statistically insignificant.

In practice, we consider a location to be authoritative when it is both reliable and accurate. The accuracy criteria are derived from the GT5 criteria. An accurate location is considered to be reliable when it can be reproduced to within 15 km, using the same dataset but different location procedures (velocity model, location algorithm).

The advantages of the proposed scheme are numerous. It depends only on the spatial distribution of the stations which have been used to compute the locations. It does not require specific criteria for border regions. Each location is evaluated independently and instantaneously, which fits within the requirements of rapid information services where

updates are numerous. The most significant improvement when compared to the previous procedures in place at the EMSC is that the new scheme does not depend on the magnitude of the earthquake. The old scheme, applied up through November, 2010, considered a location as authoritative if it was reported by only one network and located within the network geographical boundaries; Earthquakes reported by more than one network had not authoritative location and the published location was computed merging all available data. Larger earthquakes being recorded at larger distances are generally reported by several networks. Then, under the old scheme, the large earthquakes which typically attract public and media attention had no authoritative location.

The new scheme solves this problem. It was formally accepted by the EMSC General Assembly in September, 2010, and implemented in November of the same year in the EMSC real time information services.

Authoritative locations have also been identified within the Euro-Med bulletin (Godey et al., 2006) which merges 78 individual bulletins. Data contributors are encouraged to report, when possible, restricted data obtained through bilateral exchanges to ensure authoritative locations in border regions are identified as such. These restricted data are not published by the EMSC. We next plan to use the GT5 and possibly GT10 criteria to define the best dataset to be used to relocate earthquakes when no authoritative location is available.

## 4 Conclusion

The EMSC has developed and implemented a simple authoritative location scheme for its rapid earthquake information services. This development addresses a long-standing issue in public and media communications. Further improvements in the way locations are computed are also foreseen. So far, no complaints have been received from EMSC members, and the scheme seems to offer a pragmatic and satisfactory solution. The next step, and probably the biggest challenge for rapid earthquake information services, will be to propose a convincing and acceptable authoritative magnitude scheme.

## Acknowledgement

The authors would like to thank the EMSC members and the members of the IASPEI working group on authoritative locations for the fruitful discussions. We also thank Linus Kamb and Peter Bormann for improving the manuscript.

## 1 Introduction

Accurate event locations are essential for seismic hazard studies and for developing and testing three-dimensional velocity models of the Earth. However, as the main objective of producing earthquake catalogues is to achieve completeness down to the lowest detectable magnitude levels, published bulletins inevitably contain a mixture of accurate, good and poor locations. Thus, event locations in earthquake catalogues should always be treated with caution.

Published bulletins give little indication about the accuracy of the event locations. One common mistake is to consider the formal uncertainties (error ellipse, origin time and depth uncertainties) as measures of *accuracy*. The error ellipsoid provides a statistical estimate of *precision* derived from the *a posteriori* (Flinn, 1965), *a priori* (Evernden, 1969), or a mixture of the two (Jordan and Sverdrup, 1981) distributions of travel-time residuals of the observations with respect to the underlying travel-time and error-distribution models and the procedure of calculation used in the location (see Glossary terms *accuracy* and *precision*).

The calculation of formal uncertainties relies on the assumption that the error processes are Gaussian, have zero mean and are uncorrelated. Unfortunately, these assumptions are often violated in seismic locations. Picking errors may exhibit heavy tails (Buland 1986) and onset times tend to be picked late with decreasing event size (Billings et al., 1994; Douglas et al., 1997, 2005).

More crucially, travel-time predictions suffer from systematic errors due to three-dimensional velocity structures left unmodeled by the commonly used Earth models. One of the classic examples of location bias due to unmodeled 3D Earth structure is the Longshot explosion (29, October 1965, Aleutian Islands). The ray paths to nearly all stations sample the Aleutian slab, a subducted oceanic lithosphere with high seismic velocity, causing arrival-time predictions for these paths to be systematically late, which results in a 26 km location error to the north-northwest (Herrin and Taggart, 1968; Bormann, 1972). Note that such a travel-time prediction bias can be further amplified by the fact that similar ray paths from closely spaced stations will generate correlated travel-time prediction errors (Chang et al., 1983; Myers and Schultz 2000; Bondár and McLaughlin, 2009a; Bondár and Storchak, 2011).

Since the error ellipse measures precision but not accuracy, researchers considered various metrics to assess the location accuracy of events based on network geometry. We summarize these efforts below and describe the IASPEI Reference Event List maintained by the International Seismological Centre (ISC; [www.isc.ac.uk](http://www.isc.ac.uk)).

## 2 Identifying Ground Truth (GT) events

Sweeney (1996) investigated the feasibility of selecting ‘reference events’ (events where the hypocentres can be considered known to high accuracy) in continental regions from global bulletins, such as those published by the International Seismological Centre and the US Geological Survey National Earthquake Information Centre (NEIC) that contain predominantly teleseismic arrival time data. He suggested that locations from these catalogues have an accuracy of 10–15 km when the largest azimuthal gap between stations surrounding the epicenter is less than  $200^\circ$  and at least 50 first-arriving P phases are used. Sweeney (1998) revised these selection criteria and found 15 km (or better) epicentre accuracy for teleseismic networks with an azimuthal gap of less than  $90^\circ$  and with at least 50 first-arriving P phases that were used in the location.

Engdahl et al., (EHB; 1998) produced a “groomed” ISC catalogue by using the *ak135* travel-time tables (Kennett et al., 1995), later phase (including depth phases) arrival times, and station-specific travel-time corrections. Myers and Schultz (2001) estimated that the epicentre accuracy in the EHB catalogue is 15 km or better at the 95% confidence level for events not in subduction zones when the largest azimuthal gap is less than  $90^\circ$ .

Bondár *et al.* (2001) introduced the nomenclature of ‘ground truth’ categories (GT<sub>x</sub>, where ‘x’ designates epicentre location accuracy in kilometres (i.e., the true epicentre lies within ‘x’ km of the estimated epicentre) to describe the location accuracy of events in the Ground Truth data set assembled at the Prototype International Data Centre, Arlington, USA (1995-2002).

Bondár et al. (2004a) developed GT selection criteria based on network geometry to assess the location accuracy of events published in earthquake bulletins. The selection criteria identify GT5 candidate events at the 95% confidence level if they are located:

- (1) with at least 10 stations, all within 250 km;
- (2) with an azimuthal gap of less than  $110^\circ$ ;
- (3) with a secondary azimuthal gap of less than  $160^\circ$ ;
- (4) with at least one station within 30 km from the epicentre.

The GT5 selection criteria above have been successfully applied to identify GT5 candidate events by introducing the notion of secondary azimuthal gap (defined as the largest azimuthal gap which has been filled by just a single station). The secondary azimuthal gap is particularly sensitive to a station with disproportionately large data importance that may introduce location bias. The secondary azimuthal gap criterion implicitly invokes constraints on both the azimuthal gap and the minimum number of stations, but it is insensitive to clustering of stations that may generate correlated travel-time prediction error structures.

To remedy these issues, Bondár and McLaughlin (2009b) revisited the GT5 selection criteria. To avoid the *Pg/Pb* and *Pg/Pn* cross-over distance ranges, which are prone to phase identification errors, they considered stations up to 150 km only. They also introduced a new metric that measures the deviation from the optimal, azimuthally uniformly distributed network of local stations. The network quality metric is defined as the mean absolute deviation from the best-fitting uniformly distributed network of stations and the actual network. Provided that the event-to-station azimuths are sorted by increasing values, the metric is given by the expression

$$\Delta U = \frac{4 \sum_{i=1}^N |esaz_i - (unif_i + b)|}{360N}, 0 \leq \Delta U \leq 1$$

where  $N$  is the number of stations,  $esaz_i$  is the  $i$ th event-to-station azimuth,  $unif_i = 360i / N$  for  $i = 0, \dots, N - 1$ , and  $b = \text{avg}(esaz_i) - \text{avg}(unif_i)$ . The network quality metric is normalized;  $\Delta U$  is 0 when the stations are uniformly distributed in azimuth and it is 1 when all the stations are aligned at the same azimuth. Since large azimuthal gaps or potentially correlated stations (stations at similar azimuth) introduce deviations from the optimal, uniformly distributed network, the metric is sensitive to both sources of potential bias. The metric is similar to the non-parametric Kolmogorov-Smirnov statistic, which measures the maximum absolute deviation between two distributions.

The revised selection criteria identify GT5 candidate events at the 95% confidence level if an event is (re)located:

- (1) with stations within 150 km;
- (2) with  $\Delta U \leq 0.35$ ;
- (3) with a secondary azimuthal gap  $\leq 160^\circ$ ;
- (4) with at least one station within 10 km from the epicentre.

Depth and origin time typically have lower accuracy than the epicentre, since the accuracy of these parameters is not governed by the network geometry but depends on the accuracy of the velocity model as well as the availability of depth-sensitive phases (e.g., depth phases such as pP and sP, or of core reflections such as PcP). The criterion for the existence of a station virtually on top of the event is aimed to ensure that there is sufficient resolution in the data to constrain the depth, so that depth will not trade-off with the epicentre.

The Bondár et al. (2004a, 2009b) criteria were used to identify candidate GT5 events in the EHB bulletin for the IASPEI Reference Event List hosted by the ISC ([www.isc.ac.uk](http://www.isc.ac.uk)). Note that the location accuracy criteria described in this section are most relevant to continental earthquakes. Subduction zone events are likely to have a larger (and systematic) location uncertainty due to the travel-time bias introduced by the subducting slab, even if the station coverage satisfies the location accuracy criteria. Nevertheless, identifying GT5 events in subduction zones becomes more viable owing to the increasing number of ocean bottom seismometer arrays deployments worldwide. Agencies operating ocean bottom seismometer deployments are encouraged to share their data with the international scientific community.

It should be emphasized that the GT selection criteria above assume that no special effort has been made to remove location bias through the use of an optimal velocity model or path-specific travel-time predictions, or through special analysis of waveforms to improve phase picks. With such an expert seismic analysis, location accuracy of a few kilometers can be achieved (e.g. Boomer et al., 2010; Richards et al., 2006).

Detailed location studies typically make use of multiple-event methods (e.g. Douglas, 1967; Dewey 1972; Jordan and Sverdrup, 1981; Pavlis and Booker, 1983; Got et al., 1994; Waldhauser and Ellsworth, 2000; Zhang and Thurber, 2003; Engdahl et al., 2006; Bondár et al., 2008; Myers et al., 2007, 2009). Multiple event methods are known for precise *relative*

locations, but a loss of accuracy – manifested as a consistent bias for all locations – is well documented (Douglas, 1967; Jordan and Sverdrup, 1981; Pavlis and Booker, 1983). Therefore modern multiple event location techniques utilize independent GT information such as existing reference events (e.g. Ritzwoller et al., 2003; Bondár et al., 2004b), seafloor bathymetry (Pan et al., 2002), satellite imagery (e.g. Bennett et al., 2010; Fisk 2002), InSAR (e.g. Biggs et al., 2006; Parsons et al., 2006), and active fault lines (Waldhauser and Richards, 2004) to provide absolute location constraints.

Despite the utilization of multiple event methods, location precision of a few kilometers still requires the attention of an expert to construct a well-posed multiple-event problem, develop or validate travel-time models, and groom the data set.

### **3 IASPEI Reference Event List**

The IASPEI Commission on Seismic Observation and Interpretation (CoSOI) Working Group on Reference Events for Improved Locations has coordinated the global effort of collecting and validating ground truth events in the past decade. The International Seismological Centre (ISC) hosts the database of the IASPEI reference event list. Ground truth events can be searched, downloaded or submitted through the ISC website, [www.isc.ac.uk/GT/index.html](http://www.isc.ac.uk/GT/index.html).

The ISC updates the ground truth database annually. Because the ISC bulletin contains parametric data reported by various agencies with little indication of the procedures of how the actual measurements were made, it is advisable to follow a more conservative approach when identifying GT events. Therefore the Bondár and McLaughlin (2009b) ground truth selection criteria, that were specifically developed for assessing the quality of locations in a bulletin without any further special analyses, are applied to select GT candidate events from the reviewed ISC bulletin. The GT candidate events are relocated using the local stations only (within 150 km of the epicentre). The subsequent outlier analysis may reject some of the GT candidates. The members of the IASPEI CoSOI Working Group review the identified GT events, and the accepted GT events are added to the IASPEI Reference Event List. The Working Group also vets events submitted by researchers.

The IASPEI Reference Event List contains 7,410 GT0-5 events (as of August 2011) with some 525,000 phase onset time readings. The GT database consists of both earthquakes and explosions (nuclear or chemical). Figure 1 shows the number of events by type and category.

**Figure 1** Number of events by event type and GT category.

Figure 2 shows the geographical distribution of the GT events color, and symbol coded by their GT category. Note the uneven distribution of events due to the lack of dense local networks on many parts of the globe. In order to fill in gaps in GT coverage, we encourage researchers who run temporary local network deployments to submit GT event candidates. This particularly applies to Africa, South America, and South-East Asia.

**Figure 2** Geographical distribution of GT0-5 events in the IASPEI Reference Event List.

## 1 Introduction

The United Nations Decade on Natural Disaster Reduction (IDNDR; 1990-99) but also the terrible sequence of subsequent devastating earthquakes with often heavy death tolls (Izmit-Düzce, Turkey 1999; Boumerdez, Algeria 2003; Sumatra-Andaman 2004, Pakistan-Kashmir, 2005; Wenchuan, China 2008; Haiti and Chile 2010; Fukushima, Japan 2011) has in a dramatic way increased the world-wide awareness of the tremendous disaster potential of earthquakes and the urgent need for improved seismic hazard assessment, mitigation and preparedness measures. Part of these efforts is the improved monitoring and analysis of seismicity in the countries at risk, which includes improved event detection, location, magnitude determination and assuring catalog completeness down to as small as possible earthquakes (e.g., Woessner and Wiemer, 2005; Schorlemmer and Woessner, 2008; Schorlemmer et al., 2010; Kraft et al., 2011; Mignan et al., 2011).

Accordingly, the number of seismic stations and networks deployed, especially in earthquake-prone developing countries, has grown tremendously. Connected with these often costly investments in hard and software as well as qualified manpower is the expectation to get a maximum of useful information out of these “owned” physical networks, also by taking additionally into account already existing data acquisition and sharing facilities in neighbouring countries and by accessing “virtual” regional and global networks (see Chapter 8 and IS 8.3 of this Manual). In a similar way, this urgent need for fast and best quality data acquisition and information extraction also applies to the International Monitoring System (IMS) of the Comprehensive Nuclear Test-Ban Treaty (CTBT) Organization with its associated national and international components, e.g., for onsite inspection. Accordingly, related publications on the optimization of seismic networks on a local (e.g., Uhrhammer, 1980; Hardt and Scherbaum, 1994; Steinberg and Rabinovitz, 2003), regional (e.g., Kijko, 1977; Steinberg et al., 1995; Kraft et al., 2011) and global scale (e.g., Soriau and Woodhouse, 1985) have been flourishing during the last few decades.

The theoretical basis for such studies is provided by the statistical theory of optimal experimental design (e.g., Kiefer and Wolfowitz, 1960; Kijko, 1977; Silvey, 1980; Rabinovitz and Steinberg, 1990; Steinberg and Rabinovitz, 2003). This theoretical approach aims at maximizing the determinant  $\det(A^T A)$  with  $A$  the  $N \times p$  matrix of partial derivatives of observables with respect to the parameters that characterize the object under investigation, called the *D-criterion*. In the case of event location, e.g., these are the observable  $t$  (travel-

times) with respect to the 4 unknown source parameters latitude ( $\phi$ ), longitude ( $\lambda$ ), source depth  $z$  and origin time  $t_0$ . Then the D-criterion is (det of the information matrix of the hypocenter parameters) and a D-optimal network configuration maximizes the information matrix of these hypocenter parameters.

Travel-time observations may also be used for improving the Earth's velocity model (tomography) or for joint improvement of both event location and velocity structure (see IS 11.1). And other observables allow to derive improved information about other "objects" of interest, e.g., spectral amplitudes of different types of seismic waves for calculating different types of earthquake magnitude, or the 6 components of the seismic moment tensor, or observations of the distribution of P-wave polarities or amplitude ratios of P to S waves in their dependence on source azimuth and distance to derive fault plane solutions. Thus, different combinations of relevant observables with respect to looked-for parameters of the seismic sources, or of the propagation medium such as seismic velocity distribution, inhomogeneity, and anisotropy, or wave attenuation and scattering properties are in principle possible.

In recent years also algorithms of simulated annealing (SA) have been applied for calculating optimization scenarios, e.g., by Hardt and Scherbaum (1995), both for minimizing the volume of the error ellipsoid of the **linearized** earthquake location problem as well as for optimizing network configurations for best source mechanism estimates and velocity tomography studies. SA is a discrete inversion technique, such as genetic algorithms, is fast, easy to program and not restricted to the linearity of the problem. It also allows optimizing of seismic networks for difficult and combined tasks. Kraft et al. (2011), describe SA in more detail. They also extended the algorithm of Hardt and Scherbaum that was restricted to 1D layered velocity models and upgoing direct P and S waves, by

- calculating travel-times of seismic body waves using a finite difference ray tracer and the 3D velocity model of Switzerland;
- calculating seismic body-wave amplitudes at arbitrary stations using the Brune (1970) source model and using scaling relations recently derived for Switzerland, and
- estimating the noise level at arbitrary locations within Switzerland by using a first-order ambient seismic noise model based on satellite-imagery-derived land-use classes and open GIS data.

However, the complexity and degree of non-linearity of the problem increases with the number of observables and parameters to be optimized. Also, in most countries, detailed information about the local and regional velocity structure, topography, signal-to-noise conditions and other crucial boundary conditions are not yet available. This limits the full exploitation of potential benefits, which are offered by the application of more advanced optimization algorithms. Therefore, even rather recent publications, such as Steinberg and Rabinovitz (2003) still apply the simple "layers-above-half-space" model and assume that the layer thicknesses and velocities are known. They refer to Mitchell's (1974) DETMAX algorithm for the problem of finding D-optimal networks when constraints on the use of possible station sites do not permit the direct use of the "pure" theoretical results. They also have implemented these ideas in the software program OPTINET (Shimshoni et al., 1992). Thus they derive first bounds on the efficiency of any proposed network but leave the application of more complex algorithms deliberately for the time when a more detailed model parameterization is available.

This has also been our concept for the complementary PPT tutorial linked to this information sheet.

Note, that the D-criterion is applicable only for linearized design problems. Geoscientific surveys, however, are usually of a more complex non-linear nature. To handle large-scale non-linear optimization problems is still beyond current possibilities, however, respective efforts for small-scale industrial surveys are already promising. E.g., Coles and Curtis (2011) presented a new method, termed  $D_N$  optimization, for a fully non-linear Bayesian statistical experimental design. It is based on a generalization of the D criterion, takes advantage of efficient linear methods and has lower computation and data storage cost than other non-linear algorithms. When comparing their results for an optimal seafloor microseismic sensor network to monitor a fractured petroleum reservoir they could demonstrate reduced spatial bias and hypocenter uncertainty in comparison with the results of a network designed on heuristic principles and of another one based on a linearized Bayesian design. For a more general overview paper on recent advances in optimized geophysical survey design we refer to Maurer et al. (2010). However, dwelling more on non-linear design optimization is beyond the scope of this Information Sheet.

## 2 The optinet.ppt tutorial

The tutorial annexed to this information sheet outlines the very essentials of the two most common approaches to network optimization and presents some basic results derived by applying these algorithms to simplified models and sometimes restrictive boundary conditions. None-the-less, these results are more or less representative for initial network optimization calculations based on still insufficient knowledge of the seismicity, environmental, logistic and other conditions in the considered country or area of network deployment. But most importantly, the PPT aims at demonstrating that the optimization result strongly depends on both the main aim or the multiple tasks of the network as well as on the “ambient” conditions under which the network has to be installed and operated. Accordingly, **one cannot expect a unique multipurpose optimal network solution** from any theoretical approach to network optimization.

However, in order to avoid overloading the PPT presentation about principal optimization goals, algorithms and results with text and comments related to more sophisticated approaches and results we have elaborated on this in the following section of **Comments**. They are numbered in the order as they appear in red as **Comment 1, Comment 2, etc.** on the respective slides of the PPT presentation. These comments aim at qualifying or complementing some of the statements in the PPT presentation and hint to more recent (yet still linearized) optimization procedures and results of their application. Therefore, reading these comments will ease proper understanding and assessment of the PPT presentation.

The PPT tutorial can be opened from here via hyperlink by right mouse click with the cursor set in front of the file name [optinet.ppt](#). The presentation can also be downloaded via the summary listing [Download Programs & files](#) (see Overview on the NMSOP-2 cover page and follow related instructions).

### 3 Comments

#### Comment 1 on slide 4

The idealized assumption of the **first bullet point** is not an inherent requirement of the D-criterion. Rather it has to be qualified depending on the task, environmental conditions, infrastructure, data transmission links, logistic facilities, maintenance requirements, cost and other factors. When the aims and boundary conditions are better known one can “preset” a suitable or affordable number of possible station sites and then run under these refined conditions the search for an D-optimal network.

Also the assumptions made under the **second and third bullet point** are no prerequisites for applying the D-criterion. Rather, they are “set” by the way in which the matrix elements are calculated, e.g., by the algorithm used for the seismic ray-tracing. Kraft et al. (2011) base their search for a D-optimal solution on a 3D velocity model and realistic station heights. But also variable depths of borehole seismometer installations could be handled. Accordingly, also the **warning** at the end of this slide holds only for the case that the algorithm is run under the mentioned simplifying or restrictive conditions.

#### Comment 2 on slide 6

The  $v_p/v_s$  ratio tends to be more stable than the absolute velocities of P and S waves. Therefore, the joint use of P- and S-wave arrivals holds the promise of more reliable hypocentral distance and location estimates. This is usually the case for locations with modest precision requirements. However, in the case of significant variations of the  $v_p/v_s$  ratio (found out, e.g., by constructing Wadati diagrams; see IS 11.1) the inclusion of S-waves into the hypocenter location procedure would require the availability also of an independent good S-wave velocity model. Regrettably, the latter is usually not the case because of the dominating trend in both routine interactive and automatic seismogram analysis to pick only P-wave first motions. This notwithstanding, according to Gomberg et al. (1990), the inclusion of S waves is a powerful tool to significantly improve the hypocenter location accuracy and to reduce the trade-off between source depth and origin time. The most important findings of these authors can be summarized as follows:

- In the absence of detailed knowledge of the regional velocity structure, the most certain way to minimize the solution’s sensitivity to model parameter inaccuracies and theoretical simplifications is to record and pick the onsets of S phases within the aforementioned distance range.
- Using an S phase recorded close to the event almost always improves the accuracy of depth determination. E.g., including at least one reliable S-phase recorded at an epicentral distance  $D$  within about 1.4 times focal depth  $h$  yields depth estimates accurate within approximately 1.5 km. The accuracy will be only slightly inferior when the vertically averaged velocity model assumed in the location procedure differs from the true one by less than a few percent.
- In contrast, when systematic model errors are in the order of 4% and no S phases have been identified close to the source and included into the location procedure then the depth error can be larger than 3 km. This holds even in the case of good azimuthal coverage and the inclusion of several P-phases recorded at  $D < h$ .

- The largest relative improvement in focal depth accuracy is achieved in the case of poor azimuthal station coverage.
- **HOWEVER:** Just because of S-wave readings being potentially so powerful a constraint, systematic S-phase timing errors, already as small ones as 0.2 s, may degrade the accuracy of  $h$  estimates by several kilometres, even if the azimuthal coverage is good. Moreover, such S-wave timing errors may even misleadingly result in a stable - but wrong - solution with reduced standard error, i.e., improved *precision* of the solution although the actual *accuracy* is worse and may even lead to the construction of an incorrect S-wave velocity model.
- Thus, in order to take full advantage of the potential of S wave readings for improving hypocenter solutions one should aim at an optimal station spacing not larger than three times the most shallow earthquake depth which has to be determined accurately, and further, at assuring correct identification and time-picking of the S-wave onset. The latter can be assured best when readings are made on a transverse component record of sufficient dynamic range to avoid clipping.

### Comment 3 on slide 7

Experiments by Kraft et al. (2011) have shown that optimization runs for an N-station network and an N+1 network with free choice of location in both cases still show significant differences in network geometry even in the case of large N. In this sense, the procedure described in the last bullet point on slide 7 is not D-optimal for a “free” N+1 network but only in the sense of adding one station to a given network of already fixed station positions. Yet, in practice, the latter is the usually looked for.

### Comment 4 on slide 8

One major problem, which has great influence on the proposed optimal networks, is the normalization of the used objective cost functions and their relative weight with respect to other parameters. Another problem is the dependence on the random numbers and the high degree of non-linearity of systems with more than 10 stations. This requires careful tests and control of the starting conditions. E.g., Kraft et al. (2011) looked for the optimal network for hypocenter location of events down to magnitude  $M_l = 1$  in northern Switzerland by adding between 10 to 35 new stations to an existing net of 67 stations in Switzerland, Germany and Austria. Repeated optimization runs over a grid net of 952 potential station sites, separated by a spacing of some 4.5 km, yielded fluctuating results of the optimal station sites. Although their positions usually did not differ by more than two grid spacings this hints to inherent non-linearity of the problem. This made it advisable to search within these fluctuation zones of about 10 km diameter for the best suited sites. While the overall hypocentral resolution of the network configurations calculated by several optimization runs are about the same, some larger variations in the actual network geometry are possible. Generally, it is advisable to test the stability of solutions by repeated initialization of the optimization procedure.

**Comment 5 on slide 9**

One basic concept of SA (Kirkpatrick et al., 1983) is to occasionally accept "bad" solutions with  $E(j) > E(j-1)$  depending on the preset and slowly decreasing virtual temperature  $T$  of the system (termed "annealing schedule"). This allows to overrun local minima. The criterion to accept "bad" solutions is:  $\exp(dE/T) \geq \text{rand}(0, 1)$ . The criterion depends on the random number  $\text{rand}(0,1)$  and is more likely fulfilled if the virtual temperature  $T$  is high.

**Comments 6 on slide 10**

Hardt and Scherbaum (1994) considered only 1D-layered or homogeneous velocity models and stations in the distance range of Pg/Sg first arrivals, i.e., within epicentral distances typically less than about 150 km.-As said already in slide 5, for  $v = \text{const.}$  the optimal station distance radius  $r$  around the source would be infinite, because this would assure the smallest relative error in onset-time picking with respect to the total travel time. In reality the dimensions of the network are finite and determined by the scale of the problem, i.e., by the size of the search grid. Therefore, an optimal network geometry in the finite homogeneous case will consist of stations symmetrically distributed on the circumference of the search grid. This is clearly seen in the 4 solutions presented on this slide.

Further, the D-criterion tends to cluster stations at optimal sites, e.g., along the outer circumference of the search grid, if the number of looked-for stations is large with respect to the scale of the problem such as the size of the earthquake source region. This behaviour can be changed by introducing a weighting function for station spacing (e.g., Rabinowitz and Steinberger 1990). Kraft et al (2011) made use of the clustering feature of the D-criterion to identify important sites in an optimal network geometry. They performed repeated optimizations for the same large scale problem with slightly different starting conditions, i.e. re-initialized random numbers. Although the network geometries of individual runs differed due to the inherent non-linearity of the problem, stations of the different solutions were found to cluster at specific locations, which were therefore considered important optimal station sites for the considered problem. For suitable action see Comment 4 and the final comments.

In contrast to the examples shown in slide 10 with event numbers  $N_e$  less or only somewhat larger than the number of looked-for stations sites  $N_s$ , Kraft et al. (2011) searched for the best location of 10 to 35 new stations (to be added to the existing 67 stations) for locating 2240 synthetic catalog earthquakes that were equally distributed over the area under investigation. Although equal distribution of earthquakes is surely not the case in reality, this assumption assures an equally representative assessment of the resolving power of the looked-for network over the hypocentral volume covered by the network and within which earthquakes are likely to occur.

**Comment 7 on slide 15**

See last paragraph of Comments 6. The gain to be expected by later optimization according to the actually observed distribution of earthquakes is considered by T. Kraft (personal communication 2011) as likely being not so large.

**Comment 8 on slide 20**

The results of optimization strongly depend on the assumed ambient noise model. Therefore, Kraft et al. (2011) developed a first order ambient noise model for Switzerland on the basis of land-use-data derived from satellite imagery. Further, they decided to place, in a first implementation step, only part of the recommended new stations at locations with the lowest noise expected according to the three considered noise classes. With actual noise data at these stations, measured over a representative time window, they plan to update the noise model for the remaining required new station sites and to re-evaluate the initial optimization results.

However, it is often overlooked that low ambient noise does not guarantee an improved signal-to-noise ratio (SNR). Low noise hard rock sites often have also reduced signal amplitudes, whereas sites on soft rock with usually higher ambient noise typically show, especially in the short-period range, increased (up to about a factor of 10) signal amplitudes. Moreover, even for given hard-rock site the short-period SNR may, due to lateral velocity and/or topographic inhomogeneities, significantly depend on source distance and azimuth (see Chapter 4, Figs. 4.34-4.36). Investigating such site-specific signal and noise amplification has meanwhile become a widely used method for microzonation studies (see Chapter 14). Yet, these effects have so far rarely been taken into account in network optimization algorithms, although they affect especially network optimization aimed at assuring as low as possible homogeneous “completeness magnitude”  $M_c$ . Therefore, when new information about noise level and SNR conditions become available, even for a small number of the stations, then the optimization procedure should be repeated until the desired hypocentral resolution and detection/magnitude threshold sensitivity of the network is achieved.

For some newer works and results on the variable SNR and magnitude completeness problem see Mignan et al. (2010), Schorlemmer and Woessner (2008), Schorlemmer et al. (2010), Woessner and Wiemer (2005) as well as the final comments.

**Final comments related to slide 21**

With reference to slide 4 it should be mentioned that also the rather advanced Kraft et al. (2011) optimization approach does not account for correlation errors. Therefore, the resulting D-optimal networks often contained stations that were closely spaced with already existing or newly placed stations. The clustering increases with the number of stations to be placed in a network. This redundancy effect, however, can also be interpreted as an up-weighting of important placement regions for improving the hypocentral resolution. If such a cluster placement region contains already a station but with high noise (or bad average SNR) level one should either find within this placement region a better site for re-installation or consider placement of the seismometer in a shallow borehole.

Also the investigations by Kraft et al. (2011) have shown that achieving optimal network design goals for different parameters requires different network size and efforts. While for their regional network it would be sufficient to add only 10 stations to assure an epicentral resolution of 0.5 km, a minimum of 20 new stations is required to achieve a hypocentral resolution of 2 km. And the envisaged constant magnitude completeness of  $M_c = 1$  for an area of several 100 km<sup>2</sup> could only partially be achieved by adding 26 new stations. This

highlights that results from optimization algorithms, when being available already in the planning phase, may help to set more realistic goals of what can reasonably be done and provide useful guidance for final decision making prior to hardware purchases, site selection and installation efforts, depending also on available financial resources.

Although the algorithm by Kraft et al. (2011) had been developed for optimizing a rather large-scale multi-station regional network in Switzerland, it is also applicable to smaller optimization problems, e.g., for small-scale local networks aimed at surveillance of the induced seismicity from geothermal, oil or gas extraction operations, due to high-rise dam impoundment, or for volcano monitoring. Also, the algorithm is especially useful to optimize networks in populated areas with heterogeneous noise conditions, and/or complex velocity structures, as well as for complementing already existing networks. The algorithm is freely available for research and teaching from the author (contact: [toni.kraft@sed.ethz.ch](mailto:toni.kraft@sed.ethz.ch))

Finally, we have to emphasize that practically all network optimization cases discussed so far in this information sheet related to short-period high-gain systems, which are usually deployed for monitoring local and regional seismicity. However, several aspects discussed above for assuring high network performance are irrelevant or less important for long-period broadband and global seismic networks. E.g., some sites with significantly improved SNR in the short-period range and thus signal detection from weak events may show no SNR improvement at all for long-period signals (see Chapter 7, section 7.2.4.4, Fig. 7.33-7.36). Also, whereas SP sensors are rather insensitive to air-pressure, tilt and temperature fluctuations, high-gain broadband sensors requires very careful installations and shielding efforts to minimize these kinds of disturbances. However, some of the task-dependent optimal site positions identified by the algorithms may not permit to assure very stable broadband sensor placement and optimal shielding. Moreover, the optimization of the configuration of global seismic networks has to be made under rather different boundary conditions. On a global scale, earthquakes are even more inhomogeneously distributed, but also the continents and oceans, where the sensors have to be deployed. Also, the climatic, topographic, logistic and “political” environments differ more, as do the research goals when studying the whole planet Earth. This requires to consider many additional boundary conditions for optimization scenarios (e.g., Souriau and Woodhouse, 1985) as well as implementation strategies.

## 4. Final recommendations

Embarking on the optimization of seismic network configuration one should practise a step-wise and problem-/task-oriented approach. Theoretical algorithms on design optimization maybe very helpful in such efforts. Yet, one should accept that their importance lies not so much in the accuracy of their results in absolute terms, which is model-dependent and thus usually still insufficient, but rather in their qualitative value. Even answers to questions such as “Which measures may significantly improve or deteriorate the network performance?”, without giving precise numbers, may provide already useful guidance for sound decision making, as do expert recommendations based on rich seismological experience and sound intuition. The tutorial and the above comments aim at developing this needed problem understanding.

## Acknowledgment

The author owes great thanks to Dr. Toni Kraft for critical reviewing and commenting on the power point presentation and hinting to several most recent publications on network optimization. This led to the decision to complement the original PPT tutorial by a more elaborated introductory text and comment section, which were accepted in a second review.

14473 Potsdam, Germany; now: E-mail: [pb65@gmx.net](mailto:pb65@gmx.net)*

## Aim

- During the last decades the installation of seismic networks has been flourishing on local, regional and global scale.
- Efforts are made to assure best possible data products from such major investments.
- Since the 1970s theoretical modelling aimed at seismic network optimization has become fashionable.
- Yet, pretended benefits were often oversold and raised unrealistic expectations of customers.

## Therefore:

- This information sheet outlines some of the common theoretical concepts on which such optimization procedures are based as well as the assumptions that have been made to run the algorithms.
- Oversimplified assumptions or restricting conditions may not be met under real conditions.
- Moreover, optimal determination of **different** seismological parameters require **different** network configurations. Therefore, no single solution can satisfy the usually multi-purpose aim of seismic networks. ➔

- Yet, if one does not expect correct all-optimal solutions from theoretical network modelling in absolute terms but rather some guidance in a more qualitative sense for specific tasks, then such solutions may be useful.
- Two examples for specific tasks are given. For high quality location performance see also criteria outlined in IS 8.5 and 8.6. For publications, more elaborated approaches and results on network optimization see **introduction**, **comments**, and **references** in the text to this information sheet.

## Topics of this tutorial PPT:

1. Optimal configuration of seismic networks for location
2. Design of multi-task optimum networks for aftershock recordings
3. Network optimization with respect to main seismogenic faults
4. Detectability and EQ location accuracy modelling of seismic networks
5. Summary conclusions and recommendations for practical network optimization

# 1. Optimal configuration of seismic networks for location

**Approach A:** Hypocenter/epicenter positions are given  
⇒ search for **optimal siting of stations**

**Approach B:** Studying the **potential of a given network** with respect to variations in epicenter/hypocenter locations, noise conditions, addition or deletion of seismic stations

## 1.1 Statistical theory of optimal experimental design

(Kiefer and Wolfowitz, 1960; Kijko, 1977; Silvey, 1980; Rabinovitz & Steinberg, 1990)

The **D-criterion** ⇒ **maximizing  $\det(A^T A)$**  with **A** the  **$N \cdot p$  matrix** of partial derivatives which are, **in the case of event location**, the observables **t** (travel time) with respect to the **p** components of the unknown source parameters  $\varphi$ ,  $\lambda$ ,  $z$  and origin time  $t_o$

⇒ **Then the D-criterion is  $\sim \det$  of the information matrix** of the hypocenter parameters

**Thus, a D-optimal network configuration maximizes the information matrix of the hypocenter parameters.**

## Offered D-optimal solutions are often based on too simple assumptions

(yet most are not required by the D-criterion itself, but rather **aim at simplifying the algorithm**)

- e.g.:**
- stations can be placed at any location (*i.e., free choice, although it depends on the task as well as ambient and logistic conditions*)
  - stations are placed at the same height on the surface (*not suitable in terrains with rough topography*)
  - validity of a standard layered **1D velocity model** above the half-space (*although lateral velocity inhomogeneities and/or anisotropy may be significant*)
  - model errors are
    - a) uncorrelated or
    - b) correlated in a known way at closely spaced stations
- (although model inaccuracies and local anomalies are perfectly correlated at the same site and closely correlated for nearby stations)*

⇒ Design criterion is to maximize  **$\det(\mathbf{A}^T \mathbf{W}^{-1} \mathbf{A})$**  where  **$\mathbf{W}$**  is the **error correlation matrix**

**Warning:** **Such restrictive or idealized assumptions may severely limit the practical value of theoretically „optimized“ configurations**

## 1.2 Results of modelling according to the D-criterion

(for sources in the half-space)

- For a **given epicentre** • the **stations**  $\Delta$  of a D-optimal network are:
  - symmetric about the epicentre;
  - placed **equidistant on concentric circles** in agreement with „**seismological intuition**“.
- For a **given hypocentre in a half-space** the
  - triangular **quadrupartite (4-station) network**  
(according to Lilwall & Francis, 1978, and Uhrhammer, 1980)  
**is D-optimal**;
  - The **optimal radius depends on the velocity model** since the D-criterion is proportional to the take-off angle of the seismic ray from the hypocentre to the station;
  - Therefore, the radius of the „station circle“  $r \rightarrow \infty$  for  $v = \text{const.}$

- For a **hypocentre in a layer above the half-space** (single layer crust) the D-optimal configuration consists of

- **A center station** (*although now less important than in the first case, because of...*)

- **Two concentric rings** with three equidistant stations each

- The radii of the two rings have to be chosen so that the

**direct (e.g., Pg) waves** ( $\partial t/\partial z$  positive!) arrive at stations of the **inner ring** and **critically refracted waves** (e.g., Pn) ( $\partial t/\partial z$  negative!) at stations of the **outer ring**.

- Then estimates of depth  $z$  will be uncorrelated with estimates of origin time  $t_0$ .  
➔ **best estimates of source depth!**

- **Additional observations of S waves may substantially improve location** estimates, especially for sub-optimal configurations and for events outside of the network, **provided that** the ratio  $v_p/v_s$  is constant or a good  $v_s$  model is available (*which is, however, usually not the case because of the regrettably dominating routine practice of P-wave first motion picks only; see Gomberg et al., 1990*). **Comment 2!**

## 1.3 Conclusions

- When using only direct P waves, the high correlation between  $z$  and  $t_0$  **may** lead to an **ill-conditioned problem** and large uncertainty in the hypocenter estimate if the number of stations is insufficient and the network geometry bad.
- Networks with **mixed wave arrivals** (e.g., Pg and Pn) **have superior resolution**, in particular for focal depth  $z$ , since  $\partial t/\partial z$  has different signs for the upgoing direct Pg and the downgoing critically refracted Pn waves.
- This allows to design networks so that estimates of depth  $z$  will be uncorrelated with estimates of origin time  $t_0$ .
- **Additional observations of S waves may substantially improve location** under the conditions mentioned before and discussed in detail by Gombert et al. (1990).
- Adding just **one station** to an existing N-station network may already significantly improve its performance. For more detailed discussion on this issue, however, see IS 8.7 text and **Comment 3!**

## 2. Design of multi-task optimum networks for aftershock recordings

**Approach:** **Simulated annealing** (as applied by Hardt & Scherbaum, 1994)

**Prerequisite:** List of **M possible stations locations** is available (with  $M > N$ ; N-number of selected station locations)

**Challenge:** Search for **multi-task optimal network** (e.g., for EQ location, source mechanism, tomography, assuming site specific noise levels, dynamic range, frequency band of recording systems, etc.)

**Advantages:**

- **Deployment after mainshock**, i.e., the likely **area of aftershocks** is  $\pm$  **known** and thus the network aperture can be chosen such that the aftershocks falls **within the network**.
- Only local distance range with  $P_g$  and  $S_g$  as first arrivals considered.
- **Prior event scenario modelling may help (?)** to select the most appropriate design for **rapid deployment** after the event and to **upgrade** the network design in response to the actual development of the aftershock distribution.

**Difficulties:**

- The fine tuning of the annealing parameters **requires experience**.
- Multi-task **optimization is not a trivial problem** and not yet satisfactorily solved.

- The normalization of **cost functions**, their **weighting**, the high **non-linearity** of systems with more than 10 stations (→ see **Comment 4!**)

## 2.1 Method of simulated annealing (SA)

- SA is a discrete inversion technique such as genetic algorithms.
- SA is fast, easy to program and not restricted to the linearity of the problem.
- SA allows **optimizing** of seismic networks for **difficult tasks**.
- SA originates from statistical mechanics and **describes the way a liquid freezes** and forms crystals; if cooling is slow enough, nature **finds a minimum energy state**
- In seismological application **ENERGY** is replaced by the **OBJECTIVE FUNCTION (OF)** which describes the **PERFORMANCE** of a seismic network.
- Thus, the process of **SA can be applied to the problem of finding an optimum network configuration: a) for a given task; b) for a combination of tasks.**
- SA starts from a randomly chosen network configuration selected out of a list of **Np possible sites for Ns stations with  $N_p \gg N_s$** .  
(However, the **Np possible sites are usually not known before the deployment of a net but assumed, e.g., to form a dense regular grid, as in the following demonstration!**)
- For this **OF is computed**, i.e., the ‘energy state’ of the **starting configuration  $E_0$** .
- Then **step by step new configurations** are produced by moving randomly one **station** to another site.
- **New configurations** are accepted if  $dE_i = E_i - E_0 < 0$ , **until  $E_{\min} \ll E_0$  is found**.  
Nos is then the number of optimally distributed station sites
- SA accepts also **conditions** such as  $E(i) > E(i-1) \rightarrow$  **avoid getting trapped in local minima**  $\rightarrow$  see **Comment 5!**

## 2.2 SA optimal networks for hypocenter location **within** network

(Plot examples from Hardt and Scherbaum (1994) were color-coded for eased recognition)

**Red dots:** number **Ne** of assumed event epicenters; **open diamonds:** number **Np** of assumed possible station sites; **blue diamonds:** number **Nos** of calculated optimal station sites; **Ns** = number of available station sites.

**Single event**      4 Stations

- Results as for D-criterion

→ **quadrupartite network**

(forms an equal-sided triangle  
with one station in the centre)

For discussion of  
→ see **Comments 6!**

**20 events**      10 Stations

**Conclusions:** a) If event number **Ne** << **Ns** ⇒ highly redundant optimal sites;  
b) Only networks for **Ne** >> **Ns** are of interest; c) Yet: The distribution of the **Nos**  
optimal station sites depends on the **event distribution within the network!**

## 2.3 SA optimal network for determination of source mechanism

(Plot examples from Hardt and Scherbaum (1994) were color-coded for eased recognition)

- Ray penetration points on the focal hemisphere of a **single event** in the network centre to:

all 132 assumed possible stations;

20 optimum stations, which record seismic rays that homogeneously sampled the focal sphere.

Optimum 20 station network for **source mechanism** determination of a single event in the network center.

Overlay: Optimum 20 station network for **location** of this event

**Conclusion: Optimal networks for location are not optimal for source mechanism!**

## However:

- P and S waves have different radiation pattern
- Amplitude distribution within the network varies also with the
  - spatial orientation of rupture
  - source kinematics/directivity
  - source depth and velocity structure

Azimuthal **amplitude radiation pattern** for P- and S-waves from a pure vertically dipping and/or N-S/E-W trending **strike-slip fault**.

**Note:** The pattern varies with type of **source mechanism** and the specifics of rupture kinematics (slip direction, rupture speed → **source directivity**).

## Moreover:

- Most events occur outside of the network center!

Optimum **30 station network** for source mechanism

determination of **20 distributed events** •

**Overlay:** Optimum **20 station network** for source mechanism of one EQ + in network center

**Conclusion:** There is no optimal station distribution for the determination of source mechanism from distributed events with different source mechanisms!

## 2.4 Combined SA optimal network for location and source mechanism

(Plot example taken from Hardt and Scherbaum, 1994; color-coded for eased recognition)

Optimum **20 station network** for both event location and source mechanism of a **single event** • in the network center.

- This distribution is similar to a location optimal network for a single event in the network center.

**However, the solution depends on:**

- the weighting factor given to hypocenter location and source mechanism reliability, respectively;
- the velocity structure (especially with respect to the clustering near the network center for improved source mechanism;

**and**

- optimizing for many events distributed within the net changes again the configuration of “optimal sites”.

## 2.5 SA optimal network configuration for tomography

(3-D velocity and attenuation structure)

- Quality measure for tomography is the **model resolution matrix MRM** (Menke, 1989)
- Optimum resolution is obtained if the **MRM** is **diagonal**
- As **OF** one uses a **measure of diagonality** of the **MRM**, scaled between
  - 0 – for poor resolution
  - 1 – for optimum resolution
- The calculation of the MRM is rather time consuming
- **For an optimal net of 30 stations for 20 events**  
Hardt & Scherbaum (1994) calculated that this network would have  
**only < 30% optimality for tomography!**

## 2.6 Conclusions from applying SA for network optimization

- Optimized networks for **LOCATION**  $\neq$  **SOURCE MECHANISM**  $\neq$  **TOMOGRAPHY**  
 $\neq$  ???

- Hardly one knows prior to an EQ the list of **potential and accessible** sites in its future aftershock area. The location and size of this area strongly depends on the unpredictable accurate location and size of the future rupture.
- **In reality** the number of deployed stations **Ns**  $\ll$  **Ne** (number of aftershocks) and in the wake of a disaster one can hardly access predetermined “ideal locations”.
- **Aftershocks are not at all randomly distributed** within a network (but see also qualifying **Comment 7**) yet will often occur :
  - near the borders or even outside of it;
  - within an  $\pm$  elongated source volume, which is **closely related to the main rupture** and its orientation in space, and to adjacent fault systems activated due to stress redistribution in the surroundings of the main rupture.
- **Therefore**, it is more promising to **optimize location after a tomographic study** of the 3D velocity inhomogeneities in the aftershock area has been made.

## Principle of mislocation due to lateral velocity inhomogeneities

(Figure 13 of IS 11.1)

**Cartoon** illustrating systematic mislocation of earthquakes along a fault with strong lateral velocity contrast.  $v_0$  is the assumed model velocity with  $v_2 > v_0 > v_1$ .

**Note:** Events located in an inhomogeneous medium by using a laterally homogeneous velocity model are always shifted into the direction of higher velocities, the more the less homogeneous the azimuthal distribution of stations used in the location procedure.

## REAL CASE STUDY

### Epicenter maps of aftershocks of the 1997 Ms6.8 Cariaco earthquake, NE Venezuela.

Top: Results from HYPO71 locations based on a 1-D velocity-depth model.

Note the shift  
of epicenters  
from North ↓  
*before*  
towards South ↓  
*after*  
**3-D relocation**

Bottom: Relocation of the aftershocks on the basis of a 3-D model derived from a **tomographic study** →  
of the aftershock region (Figure 11 of IS 11.1, courtesy of M. Baumbach, H. Grosser and A. Rietbrock, 2001).

**Note** the significantly higher P-wave velocities towards North !

**Note** the excellent linear alignment of most aftershocks with depth along the Cariaco fault system in the center area of good tomographic control and resolution and the wide scatter of hypocenter locations outside this area of good network coverage. (where deviations of velocity from the average model can not be resolved).

**3-D distribution of the P-wave velocity** in the focal region of the 1997 Cariaco earthquake as derived from a tomographic study. The map view shows the velocity distribution in the layer between 2 km and 4 km depth. Red and blue dots mark the epicenters of the aftershocks. The red ones were chosen because of their suitability for the tomography.

**Vertical cross sections** showing the depth distribution of the aftershocks (green dots) together with the deviations of the P-wave velocity from the average reference model. The depth range and the lateral changes of fault dip are obvious (Figure 12 of IS 11.1, courtesy of M. Baumbach, H. Grosser and A. Rietbrock, 2001).

### 3. Network optimization with respect to main seismogenic faults

(Case study by Steinberg et al., 1995)

- Tasks:**
- Reduction of an existing network from 17 stations to 6-8 station sites
  - Optimal 6-8 stations for monitoring the two main faults “Bekaa” and “Yagur”

Optimal six-station network (out of 17 existing stations) for monitoring the “Bekaa” fault (**yellow**) and “Yagur” fault (**blue**), as well as of an optimal eight-station network monitoring both fault systems (**red**) (according to Steinberg et al., 1995)

## 4. Detectability and EQ location accuracy modeling of seismic networks

according to Živčić and Ravnik (see IS 7.4)

### Allows to calculate accuracy of event location:

- within and nearby outside of network;
- for different hypocenter depth and EQ magnitudes (i.e.,  $\neq$  SNR and accuracy of time picking; see also **Comment 8**).
- to recalculate network performance when configuration and/or number of station is changed.

### Assumptions:

- Station coordinates are exactly known;
- RMS value of noise in the used frequency range is known;
- instrument response flat between 1 - 10 Hz;
- P- and S- arrival times picked with known accuracy;
- P and S velocity model known (with some uncertainty);
- small local network which allows to use the flat Earth approximation.

Result of model calculations for the Stareslo network in Slovenia for  $M_l = 1.0$  earthquake.

Red triangles: station positions

Blue lines: borders of Slovenia,

Thin black lines: isolines of **hypocenter location error in km**;

Thick black line outer boundary: outer limit of the network's location capability for earthquakes of  $M_l = 1.0$ .

The **computer program LOK** by Živčić and Ravnik is described in more detail in IS 7.4 and can be downloaded from there.

## 5. Summary conclusions and recommendations for network optimization

1. **Theoretically optimal network geometries** obtained under idealized assumptions or restricting conditions **may not be optimal under real conditions** of

- spatially distributed,  $\pm$  irregular seismicity patterns;
- significant variations in velocity structure;
- strongly varying SNR conditions even at “optimal sites” (see **Comment 8!**);
- unaccessibility or other limitations of “optimal sites” due to lacking infrastructure and power supply, rough topography, bad site geology, data-link problems etc.

2. Station distributions should provide a **good azimuthal coverage** with gaps  $\leq 120^\circ$  and **nearly equidistant** spacing forming  $\pm$  equal-sided station triangles.

3. **Good depth estimates** require at least **one station near epicentre** (at  $D < 2$  h), or **stations both in the Pg and Pn distance range, or well identified depth phases.**

**THEREFORE: priority should be given to:**

- **Meeting conditions 2. and 3.** together with comparably **good detectability thresholds** (SNR) at the various stations/subnets as far as possible;

- **later object and/or problem-oriented optimization of existing networks** by addition or deletion of stations based on better knowledge of **seismicity patterns, velocity inhomogeneities, SNR, chief aim of study, financing** etc. (**see Final Comments**).

## 9.1 Outline

When the Manual of Seismological Observatory Practice (Willmore, 1979) was published, only a small number of seismic arrays with open data access were in operation. At the time, array seismology was limited to a very small number of specialists and, as a result, the chapter on array seismology in that issue of the Manual comprised just two pages, including one figure. Over the last three decades, many new seismic arrays have been deployed globally and, due to improvements in digital data acquisition systems and digital signal processing, it has become much easier to handle the large amount of data generated by seismic arrays. Array data have also become more easily accessible, and some array data are now even available in near real-time via SEEDlink servers. Consequently, array observations have now become more common in the seismological community. This chapter on array seismology explains the principles of seismic arrays and how array data can be used to analyze different types of seismic signals.

In the following sections, we define the term “seismic array” and show examples of seismic arrays installed around the world. We then describe the theoretical basics of the processing of seismic data observed with an array, continue with the explanation of tools for the analysis of transient signals and ambient noise observed with seismic arrays and describe some considerations in the optimization of seismic array configurations, in order to provide guidance for new array installations. We explain how seismic, in particular local and regional, events are located at the NORSAR Data Processing Center using only single array observations and, finally, discuss the application of seismic arrays to earthquake early warning systems.

## 9.2 Introduction

“The Conference of Experts to study the methods of detecting violations of a possible agreement on the suspension of nuclear tests” held in 1958 in Geneva under the auspices of the United Nations, was followed by several initiatives for improving the quality of seismic stations worldwide. At the same time, the idea of installing arrays of sensors to improve the Signal-to-Noise Ratio (SNR) of seismic onsets was adopted from radio astronomy, radar, acoustics, and sonar. In the 1960s, it was demonstrated that seismic arrays could facilitate detection and characterization of seismic signals that was superior to that possible using single three-component stations. Today, many of the seismic stations of the International Monitoring System (IMS) for the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) (see e.g., Dahlman et al., 2009) are arrays.

Seismic arrays were used to investigate the nature and source regions of microseisms (e.g., Capon, 1969b; Lacoss et al., 1969; Cessaro, 1994; Friedrich et al., 1998; Essen et al., 2003; Schulte-Pelkum et al., 2003). Since the 1980 (see e.g., Furumoto et al., 1990; Chouet, 1996; Almendros, 1997), seismic arrays have also become a tool for locating and tracking volcanic tremor and for analyzing complex seismic wave-field properties in volcanic areas (see also Section 13.4.4 in Chapter 13). Not only usual seismometers but also strong motion instruments (often sensitive to ground accelerations) have been installed in array configurations to study near field effects of earthquakes (see e.g., Spudich and Cranswick (1984); Abrahamson et al., (1987); Goldstein and Archuleta (1991b); Chiu et al., (1994); Huang (2001); or more recently Halldorson et al., 2009). For borehole installations of strong-motion sensors in array configurations see Section 7.4.6 of Chapter 7. Another possible application of seismic arrays was shown by Frankel et al. (1991), who used a temporary, very small aperture array to track aftershock activities after the 1989 Loma Prieta earthquake.

A seismic array is a set of seismometers deployed so that characteristics of the seismic wavefield at a specified reference point, within or close to the array, can be inferred by analyzing the waveforms recorded at the different sites. A seismic array differs from a local network of seismic stations mainly by the techniques used for data analysis. Thus, in principle, a network of seismic stations can be used as an array, and data from an array can be analyzed as data from a network. The size of an array is defined by its aperture, which is the largest horizontal distance between two sensors of the array. In practice, the geometry and the number of seismometer sites of an array are determined by the intended scientific purpose and economic limits. Details about array configurations can be found e.g., in Barber (1958; 1959), Haubrich (1968), Harjes and Henger (1973), or in Mykkeltveit et al. (1983; 1988).

Most array processing techniques require high signal coherency across the array, and this imposes signal frequency dependent constraints on the array geometry (spatial extent) and instrumentation. A homogeneous geology below all sites of the array is preferable since geological heterogeneity will diminish waveform semblance. Furthermore, proper analysis of array data depends on a stable, high precision relative timing of all array elements. This is required because most of the parametric information calculated using the array involves the measurement of (usually very small) time differences (phase shifts) between the seismic arrivals on the different sensors.

The superior signal detection capabilities of seismic arrays result from the use of so-called “beamforming” techniques whereby the signals at different sensors are delayed and stacked. The SNR is enhanced since the signals interfere constructively whereas the (random)

background noise is suppressed. Arrays can also provide estimates of the station-to-event azimuth (backazimuth, BAZ) and the apparent velocity of the seismic signals. These estimates are important both for event location purposes and for signal identification and classification, e.g., as P, S, local, regional, or teleseismic phases.

In principle, the slowness resolution of an array – i.e., how accurately the direction and apparent velocity of an incoming wavefront can be measured – improves with increasing the array aperture. However, the signal coherency diminishes with increasing sensor separation and so the spatial extent of an array is usually specified to provide an optimal trade-off between coherency and theoretical slowness resolution.

In this chapter we describe procedures for estimating the apparent wavefront velocity (inverse of the slowness or ray parameter), the angles of approach (backazimuth and incidence angle; cf. Figs. 9.8 and 9.9 in this Chapter) of a seismic signal as well as basic processing algorithms for signal detection, one-array regional phase association, and the preparation of an automatic event bulletin. Throughout the text, we use data processing examples from the large NORSAR array (NOA) in southern Norway and from the “regional” arrays NORES in southern Norway, ARCES in northern Norway and GERES in southeast Germany.

There have, historically, been few publications that provide tutorial details about basic array processing. There are numerous papers detailing advanced techniques and presenting results from observations, but the basics of beamforming and STA/LTA detection processing are mostly assumed to be known. The processing algorithms used are similar to many types of signal-processing applications and time-series analysis in fields such as radar technology (e.g., Barber, 1958; 1959) and in seismic prospecting. In seismic prospecting, “beamforming” is called “stacking”.

The basic processing techniques developed in the 1960s have survived, and are still in use. The *Seismic Array Design Handbook* (IBM, 1972) describes the processing algorithms for the arrays LASA and NORSAR (today NOA). References therein are mostly to reports prepared by J. Capon and R. T. Lacoss of Lincoln Laboratories. A description of many array methods and early array installations can be found in a proceedings volume (Beauchamp, 1975) of a NATO Advanced Study Institute conference in 1974 in Sandefjord, Norway. In 1990, a special issue of the *Bulletin of the Seismological Society of America* was published (Volume **80**, Number 6B) with contributions from a symposium titled “Regional Seismic Arrays and Nuclear Test Ban Verification”. This issue contains many papers on theoretical and applied array seismology. More recent reviews on array applications in seismology can be found in e.g., Douglas (2002), Gibbons et al. (2009) or Rost and Thomas (2002; 2009). Since the 1970s, NORSAR has published Semiannual Scientific Reports, and several issues of this series cover array data processing techniques and their applications. A special issue on “Array seismology in Europe: recent developments and applications” was published in 2011 in the *Journal of Seismology* (for an overview see Schweitzer and Krüger, 2011).

At the NORSAR Data Processing Center (NDPC) at Kjeller, Norway, data have been acquired for many years from different types of arrays: e.g., the large aperture NORSAR array (today NOA), the small aperture arrays NORES and ARCES and the very small aperture array on Spitsbergen (SPITS). We describe the general array-processing techniques for training purposes and for use as a reference for analysts new to the field of seismic array processing. Some algorithms are described in detail, whereas others have references to available

literature. It is assumed that the reader has a basic knowledge of time-series analysis such as bandpass filtering and Fourier transforms (e.g., Buttkus, 2000; Scherbaum, 2001).

Communication technologies for data transmission (in near real time) between the arrays sites and data processing centers are now available and cost effective. The volume of data generated by an array of seismometers and the associated digital signal processing no longer represent insurmountable technical difficulties. However, low-threshold detection processing leads to large numbers of triggers, all of which require analysis. It is therefore of great importance to use techniques that are robust and easy to operate in an automatic, uninterrupted mode. Three main stages of automatic data processing are employed at the NDPC:

- Detection Processing (DP), which uses beamforming, filtering and STA/LTA detectors to define signal triggers;
- Signal Attribute Processing (SAP), which uses techniques such as frequency-wavenumber ( $f$ - $k$ ) analysis to estimate the slowness vector, and other techniques to estimate parameters such as the onset time, period, amplitude and polarization attributes for every trigger; and
- Event Processing (EP), which analyzes the attributes and sequence of triggers to associate seismic phase arrivals to define events.

A documentation of these processing steps can be found in Mykkeltveit and Bungum (1984) with results from a first version of a program (called RONAPP) for detecting and associating seismic signals from regional events using data from the small aperture, regional array NORES. Later, the NORSAR processing was re-coded to adapt to any array, several data formats and machine architectures. These algorithms are packaged into the programs DP for continuous detection processing, and EP for automatic signal attribute processing, event processing, and interactive special processing (Fyen, 1989; 2001a and b). These programs have been used for almost all examples herein. Section 9.13 shows and explains the output of this automatic data processing for some signals observed with the ARCES array as an example of routine array data analysis.

## 9.3 Examples of seismic arrays

To the best of our knowledge, the first experimental seismic array with more than four elements and openly available data was established in February 1961 by the United Kingdom Atomic Energy Agency (UKAEA) on Salisbury Plain (UK), followed in December 1961 by Pole Mountain (PMA, Wyoming, USA), in June 1962 by Eskdalemuir (EKA, Scotland, UK), and in December 1963 by Yellowknife (YKA, Canada). These types of arrays (the so-called UK-arrays) are orthogonal linear or L-shaped. Later, arrays of the same type were built in Australia (Warramunga), Brazil (Brasilia), and India (Gauribidanur). A detailed description of this type of arrays can be found in Keen et al. (1965), Birtill and Whiteway (1965), and Whiteway (1965; 1966). Fig. 9.1 shows the configuration of the Yellowknife array (Somers and Manchee, 1966; Manchee and Weichert, 1968; Weichert, 1975) as one example of this kind of medium-sized array, which is still in operation. The apertures of the UKAEA arrays vary between 10 and 25 km.

**Fig. 9.1** Configuration of the UKAEA - type Yellowknife array (YKA) in Northern Canada. The blue and the red sites have vertical short-period instruments, while three-component, broadband seismometers are installed at the green sites. The center seismometer of YKA has the geographic coordinates 62.4932°N, 114.6053°W.

Since the 1950s, classified arrays deployed to monitor nuclear test activities at teleseismic distances had been built worldwide. Many of these arrays became known in the 1990s and are today part of the IMS as primary or auxiliary stations, e.g., AKASG (Malin, Ukraine), ASAR (Alice Springs, Australia), BRTR (Keskin, Turkey), CMAR (Chiang Mai, Thailand), ESDC (Sonseca, Spain), ILAR (Eielson, Alaska), and KURK (Kurchatov, Kazakhstan). Many of these arrays have quite diverse geometries and in some cases comprise different installations for short and long period signals (e.g., the Belbaşı and the Keskin array: Kuleli et al., 2001; Semin et al., 2011).

In the 1960s, arrays with very different apertures and geometries were tested, from small circular ones with apertures of a few kilometers to huge arrays with apertures of up to 200 km. The largest arrays were the Large Aperture Seismic Array (LASA: Frosch and Green, 1966) in Montana (USA), opened in 1965 and in operation until 1978 with 525 seismometer sites, and the original Norwegian Seismic Array (NORSAR: Bungum et al., 1971) in southern Norway, consisting of 132 sites over an aperture of approximately 100 km with altogether 198 seismometers, which became fully operational in spring 1971. The original NORSAR array was reduced in 1976 to seven subarrays (see Fig. 9.2) and was assigned the new code name NOA.

Figs. 9.2 and 9.3 show the configurations of the present day NORSAR (NOA) and NORES arrays and the layout of the seismometer sites for the ARCES array. The NORES and ARCES-type array design with sites located on concentric rings (each with an odd number of sites) spaced at log-periodic intervals is now used for most of the modern small aperture arrays; only the number of rings and the aperture (diameter of the outermost ring of sites) differ from installation to installation. For example, the SPITS array has only nine sites and

corresponds to the center site plus the A- and the B-ring of a NORES-type array; the FINES array in southern Finland consists of three rings with 16 sites altogether. The geometry of these regional, relatively small arrays was developed in the 1980s and 1990s. Today, the configuration of a SPITS-type 9-element array constitutes the standard for new arrays in the IMS, but in general with a larger aperture than SPITS.

## NOA and NORES

**Fig. 9.2** Configuration of the present day large aperture NORSAR array (NOA) and the small aperture array NORES. The NORES array is co-located with the NORSAR subarray NC6. The aperture of NOA has, since 1976, been about 60 km and the aperture of NORES is about 3 km (see the small blue symbols). Each seismometer site is marked with a circle. The present NOA configuration has 42 sites, whereas the NORES array has 25 sites. NOA has seven subarrays, each with six vertical seismometers installed in shallow boreholes. In addition, one site in each subarray (marked in green) has one three-component broadband seismometer. The geometry of NORES is identical to the geometry of ARCES shown in Fig. 9.3. The center seismometer of NOA in subarray NB2 has the geographic coordinates 61.03972°N, 11.21475°E. The center seismometer of NORES has the geographic coordinates 60.73527°N, 11.54143°E.

**Fig. 9.3** Configuration of the regional array ARCES, which is identical to the NORES array. Each vertical short-period seismometer site is marked with a circle and a cross. The ARCES array has 25 sites with vertical short-period seismometers. Four of these sites have in addition short-period horizontal seismometers. These short-period three-component sites are marked in blue or red. A broadband three-component seismometer is co-located with the short-period three-component seismometer at the center site (red). ARCES has one center instrument – ARA0 – and four rings: the A-ring with three sites and a radius of about 150 m, the B-ring with five sites and a radius of about 325 m, the C-ring with seven sites and a radius of about 700 m, and finally, the D-ring with nine sites and a radius of about 1500 m. The center seismometer of ARCES has the geographic coordinates 69.53486°N, 25.50578°E. The table on the right of the figure gives the relative coordinates between the single sites and the center site ARA0, and the elevation of all sites above sea level in meters.

The large LASA and NORSAR arrays and the UKAEA arrays had narrow-band short-period seismometers at all sites and additional long-period seismometers at selected sites in their original configurations, whereas the Gräfenberg Array (GRF) in Germany was planned and installed in the early 1970s as an array of broadband sensors. It has an aperture of about 100 km (Harjes and Seidl, 1978; Buttkus, 1986) and an irregular shape (Fig. 9.4) that follows the limestone plateau of the Franconian Jura.

**Fig. 9.4** Configuration of the irregularly shaped Gräfenberg array (GRF). Since several years, all sites are equipped with three-component, broadband STS-2 seismometers. The green line follows the geological unit Franconian Jura, on which the array is located. The reference station GRA1 (at position A1 on the map) has the geographical coordinates 49.69197°N and 11.22200°E.

Another approach to arrays was developed in the 1990s. In parts of Japan and in the USA the networks of seismometer stations are so dense that data from all stations can be combined and used as array data. Examples of these are the so-called J-array, the Californian array and the ongoing USArray project with semi-temporary stations (Levander et al., 1999). All known array techniques can be applied to analyze data from these networks (see e.g., J-array Group, 1993 or Benz et al., 1994).

## 9.4 Beamforming

With an array we can improve the signal-to-noise ratio (SNR) of a seismic signal by summing the coherent part of seismic signals as observed at the different single array sites. Figs. 9.5 and 9.6 show P onsets of a regional event observed at the ARCES sites and, in addition, the summation trace (on top) of all single observations divided by the number of traces. In Fig 9.5 the data were summed without taking into account any signal delay times between the

different stations due to finite apparent velocity of wave propagation. Consequently, the P onset is suppressed by destructive interference. In Fig. 9.6 all traces were time-adjusted to provide alignment of the first P pulse before summation. Note the clear and short P pulse on the beam trace and the suppression of incoherent energy in the P coda and preceding noise. In the following, all calculations of summation traces always includes as a last processing step the division of the summation trace by the number of traces summed up. This is done to conserve the amplitude of seismic signals for any later signal analysis.

**Fig. 9.5** The figure shows P-phase onsets of a regional event observed with the vertical short-period seismometers of ARCES. The top trace is an array beam, and the remaining traces are single vertical short-period seismograms. All data were filtered with a Butterworth band pass filter between 4 and 8 Hz and are shown with a common amplification. All traces were summed to create the beam, which was then divided by the number (23) of traces, without any delay-time application.

This demonstrates that the most significant consideration in the summation (or beamforming) process is to find the best delay times, with which the single traces must be shifted before summation (“delay and sum”) in order to get the largest amplitudes due to coherent interference of the signals. The simplest way is just to pick the onset times of the signal on each trace and shift the traces with respect to the onset time at the reference site of the array. However, most onsets from weaker events have a much smaller SNR than in the example shown, and therefore onset times are often difficult to pick. With hundreds of onsets each day, this is not practical during routine operation. Therefore for routine processing of array data the best approach is to predefine many different beams and to calculate them automatically. A detector can then search for onsets on these beams.

**Fig. 9.6** This figure shows P-phase onsets of a regional event observed with the vertical short-period seismometers of ARCES as in Fig. 9.5 but the single traces were first aligned, summed up and then divided by the number of traces (23). Note for this case the clear and relatively short pulse form of the first P onset on the beam and the suppression of incoherent energy in the P coda.

In the following sections, we explain how such delay times can be theoretically calculated for known seismic signals, using some basic equations and parameter definitions, and we give the formulas for a seismic beam.

### 9.4.1 Geometrical parameters

As aforementioned, an array is defined as a set of seismometers with one seismometer site or any other location within or close to the array being assigned the role of a reference point. The relative distances from this reference point to all other array sites are used later in all array specific analysis algorithms (Fig. 9.7).

$\mathbf{r}_j$  Position vector of instrument  $j$  with a distance (absolute value)  $r_j$  from the defined reference point. We use bold characters for vectors and normal characters for scalars. The position is normally given relative to a (central) instrument at site  $O$ ,  $\mathbf{r}_j = f(x, y, z)$ , where  $(x, y, z)$  are the Cartesian coordinates measured in [km] with positive axes towards East ( $x$ ), towards North ( $y$ ), and in the vertical up above sea level ( $z$ ).

**Fig. 9.7** Illustration (horizontal plane) of an array of instruments (filled circles). The center instrument  $0$  is used as reference and origin for the relative coordinates  $x$ ,  $y$  (see also Fig. 9.3 for an example of such a circular array).

**Fig. 9.8** Definition of the angles  $\Theta$  (direction of wavefront propagation) and  $\Phi$  (direction to the epicenter = backazimuth); here, e.g., for a wavefront coming from north-east and crossing the array in a south-westerly direction.

For distances from the source much larger than about 10 wavelengths, a seismic wave approaches an array as a **wavefront** that is close to **planar**. The case when the (simplified) plane-wave approach is no longer applicable and a circular wavefront has to be assumed is discussed in Almendros et al. (1999). The directions of approach and propagation of the wavefront projected on to the horizontal plane are defined by the angles  $\Phi$  and  $\Theta$  (Fig. 9.8).

- $\Phi$  Backazimuth (often abbreviated as BAZ) = angle of wavefront approach, i.e., direction angle from a station to an epicenter, measured clockwise from the North to the direction towards the epicenter in  $[\circ]$ . In many cases this angle is for short called azimuth, but the recommendation is to use in all cases backazimuth to distinguish it from other azimuth measures.
- $\Theta$  Direction in which the wavefront propagates, also measured in  $[\circ]$  from the North, with  $\Theta = \Phi \pm 180^\circ$ .

**Fig. 9.9** Illustration (vertical plane) of a seismic plane wave crossing an array at an angle of incidence  $i$ .

In the vertical plane, the angle measured between the direction to the source and the vertical is called the angle of incidence  $i$  with  $i \leq 90^\circ$  (see Fig. 9.9). The seismic velocity below the array in the uppermost crust and the angle of incidence define the apparent propagation speed of the wavefront crossing the array. Be aware that the seismic velocity below the array is an effective mean velocity of the uppermost crustal layers depending on the dominant wavelength (frequency) of the seismic signal.

### 9.4.2 Apparent velocity and slowness

The upper crustal velocity together with the angle of incidence defines the apparent propagation speed of the wavefront at the observing instruments. This is **not** the physical propagation speed of the wavefront and is therefore called **apparent** velocity (see also Section 2.5.2 of Chapter 2). We start our consideration by defining the following quantities (for definition see Fig. 9.9):

- $d$  horizontal distances between different array sites in [km];
- $v_c$  effective, mean crustal velocity (for P or S waves, depending on the seismic phase) immediately below the array in [km/s];
- $i$  angle of incidence;

- $\mathbf{v}_{app}$  apparent velocity vector with the absolute value  $v_{app} = 1/s$ .  $\mathbf{v}_{app} = (v_{app,x}, v_{app,y}, v_{app,z})$ , where  $(v_{app,x}, v_{app,y}, v_{app,z})$  are the single apparent velocity components in [km/s] of the wavefront crossing an array;
- $v_{app}$  absolute value of the apparent velocity vector in [km/s] of a plane wave crossing an array (see Fig. 9.10);
- $v_{app,h}$  absolute value of the horizontal component of the apparent velocity
- $$v_{app,h} = \sqrt{v_{app,x}^2 + v_{app,y}^2}.$$

The inverse of the apparent velocity  $v_{app}$  is called slowness  $s$ , which is a constant for a specific ray. For local or regional applications the unit of slowness is [s/km]. For global applications it is more appropriate to use the unit [s/°] and slowness is then called ray parameter. The ray parameter of major seismic phases is usually tabulated for standard Earth models together with the travel times as a function of distance from the source. The following symbols are used:

- $\mathbf{s}$  slowness vector with absolute value  $s = 1/v_{app}$ .  $\mathbf{s} = (s_x, s_y, s_z)$ , where  $(s_x, s_y, s_z)$  are the single, inverse apparent velocity (= slowness) components in [s/km]. Note, because the vector  $\mathbf{s}$  is oriented in the propagation direction (in direction of  $\Theta = 225^\circ$ , see Fig. 9.8), a plane wave with backazimuth  $\Phi = 45^\circ$  would have negative values for both horizontal components with North and East directions being positive;
- $s$  absolute value of the slowness vector in [s/km] of a plane wave crossing an array;
- $p$  ray parameter  $p = s \cdot g$ , measured in [s/°], for a spherical Earth model with a radius of 6371 km, where  $g = \frac{\pi \cdot 6371 \text{ km}}{180^\circ} \cong 111.19 \text{ [km/°]}$ .

The relation between the parameters of a plane wave and the actual seismic signal is given by the wavenumber vector  $\mathbf{k}$ :

- $\mathbf{k}$  wavenumber vector defined as  $\mathbf{k} = \omega \cdot \mathbf{s}$  with the angular frequency  $\omega = 2 \cdot \pi \cdot f = 2 \cdot \pi / T$  measured in [1/s].  $T$  is the period and  $f$  the frequency of the seismic signal;
- $k$  absolute value of the wavenumber vector  $\mathbf{k}$  defined as  $k = \omega \cdot s = 2 \cdot \pi \cdot f \cdot s = 2 \cdot \pi / \lambda$ , measured in [1/km].  $\lambda$  is the wavelength of the signal and because of the analogy between  $\omega$  and  $k$ ,  $k$  is also called spatial frequency.

The time delay  $\tau_j$  is defined as the arrival-time difference of the wavefront between the seismometer at site  $j$  and the seismometer at the reference site. The unit of measurement is seconds with a positive delay meaning a later arrival with respect to the reference site.

Assume a wavefront is propagating the distance  $l$  between time  $t_1$  and time  $t_2$  (Fig. 9.9). Then, if  $d$  is used for the horizontal distance between instrument 1 and 2 in [km], and if both instruments are assumed to be at the same elevation, we have:

$\tau_2 = (t_2 - t_1) = \frac{l}{v_c}$ , and the horizontal component of the apparent velocity  $v_{app,h}$  is then defined as a function of the incidence angle  $i$  (Fig. 9.10):

$$v_{app,h} = \frac{d}{(t_2 - t_1)} = \frac{v_c}{\sin i} \quad v_{app,z} = \frac{v_c}{\cos i} \quad (9.1)$$

**Fig. 9.10** A plane wave propagating in the direction of the green arrow with the velocity  $v_c$  reaches the Earth's surface. The decomposition of this velocity into a vertical ( $v_{app,z}$ ) and a horizontal component ( $v_{app,h}$ ) of the apparent velocity depends on the incidence angle  $i$ . The horizontal velocity component is only equal to the propagation velocity  $v_c$  for waves propagating parallel to the surface; in all other cases  $v_{app}$  is higher than  $v_c$ .

**Fig. 9.11** Illustration (horizontal plane) of a plane wave, coming from the Southwest (backazimuth  $\Phi$ ), crossing an array and propagating in a north-easterly direction  $\Theta$ .

### 9.4.3 Plane-wave time delays for sites in the same horizontal plane

In most cases, the elevation differences between single array sites are so small that travel-time differences due to elevation differences are negligible (Fig. 9.9). We can assume, therefore, that all sites are in the same horizontal plane. In this case, we cannot measure the vertical component of the wavefront propagation. The vertical apparent velocity component can then

be defined as  $v_{app,z} = \infty$ , and the corresponding slowness component becomes  $s_z = 0$ . From Fig. 9.11 we see that the time delay  $\tau_4$  [s] between the center site 0 and site 4 with the relative coordinates  $(x_4, y_4)$  is

$$\tau_4 = \frac{d_4}{v_{app,h}} = \frac{r_4 \cdot \cos \beta}{v_{app,h}}, \text{ with } r_4 = |\mathbf{r}_4|.$$

Now let us omit the subscript 4, and evaluate further:

$$\begin{aligned} \alpha + \beta + \Theta &= 90^\circ, \quad r \cdot \cos \beta = d, \quad r \cdot \cos \alpha = x, \quad d = \frac{x \cdot \cos \beta}{\cos \alpha} \\ d &= \frac{x \cdot \cos(90^\circ - \alpha - \Theta)}{\cos \alpha} = \frac{x \cdot (\sin \alpha \cdot \cos \Theta + \cos \alpha \cdot \sin \Theta)}{\cos \alpha} = x \cdot \frac{\sin \alpha}{\cos \alpha} \cdot \cos \Theta + x \cdot \sin \Theta \\ d &= x \cdot \frac{y}{x} \cdot \cos \Theta + x \cdot \sin \Theta = y \cdot \cos \Theta + x \cdot \sin \Theta \end{aligned}$$

With  $\Theta = \Phi \pm 180^\circ$  (Fig. 9.8), we get for the horizontal distance traveled by the plane wave  $d = -x \cdot \sin \Phi - y \cdot \cos \Phi$ .

Then, for any site  $j$  with the horizontal coordinates  $(x, y)$ , but without an elevation difference relative to the reference (center) site, we get the time delay  $\tau_j$ :

$$\tau_j = \frac{d_j}{v_{app,h}} = \frac{-x_j \cdot \sin \Phi - y_j \cdot \cos \Phi}{v_{app,h}} \quad (9.2)$$

These delay times can also be written in vector syntax with the position vector  $\mathbf{r}_j$  and the slowness vector  $\mathbf{s}$  as parameters. In this notation the delay times are defined as projection of the position vector onto the slowness vector:

$$\tau_j = \mathbf{r}_j \cdot \mathbf{s} \quad (9.3)$$

#### 9.4.4 Plane-wave time delays when including site elevations

In some cases, not all array sites are located on one horizontal plane. Then the calculation of the time delays becomes slightly more complicated. Site 2 (Fig. 9.12) has the relative coordinates  $(x_2, y_2, z_2)$  and we see that  $i + \gamma + \varphi = 90^\circ$ ,  $z_2 = r_2 \cdot \sin \varphi$ ,  $d_2 = r_2 \cdot \cos \varphi$ ,  $l = r_2 \cdot \cos \gamma$ , and  $\tau_2 = \frac{l}{v_c}$ .

$$l = \frac{z_2}{\sin \varphi} \cdot \cos \gamma = \frac{z_2}{\sin \varphi} \cdot \cos(90^\circ - i - \varphi) = \frac{z_2 \cdot (\sin i \cdot \cos \varphi + \cos i \cdot \sin \varphi)}{\sin \varphi}$$

Omitting again the site number, we get:

$$l = z \cdot \frac{\cos \varphi}{\sin \varphi} \cdot \sin i + z \cdot \cos i = d \cdot \sin i + z \cdot \cos i$$

Using Eqs. (9.1) and (9.2), we get for the total time delay at site  $j$

$$\tau_j = \frac{-x_j \cdot \sin i \cdot \sin \Phi - y_j \cdot \sin i \cdot \cos \Phi + z_j \cdot \cos i}{v_c} = \frac{-x_j \cdot \sin \Phi - y_j \cdot \cos \Phi}{v_{app}} + \frac{z_j \cdot \cos i}{v_c} \quad (9.4)$$

**Fig. 9.12** Illustration (vertical plane) of a plane wave crossing an array at the angle of incidence  $i$ .

Now, the time delays  $\tau_j$  also depend on the local crustal velocities ( $v_c$ ) below the given site  $j$  and not just on the parameters of the wavefront ( $\Phi, v_{app}$ ). This is a clear disadvantage of arrays where single sites are not located on one horizontal plane, and if possible elevation variations should be avoided when planning a new array installation. Writing these time delays in vector notation will again result in Eq. (9.3), but note, the vectors are now three-dimensional.

$$\tau_j = \mathbf{r}_j \cdot \mathbf{s}$$

As rule of thumb one can use: elevation corrections should be applied whenever elevation related time delays between different array sites become equal or larger than about  $\frac{1}{4}$  of the dominant signal period.

### 9.4.5 Beamforming formulae

After deriving the delay times  $\tau_j$  for each station by solving Eq. (9.2) or Eq. (9.4) for a specific backazimuth and apparent velocity combination, we can define a “delay and sum” process to calculate the array beam. In the following we will use the shorter vector syntax of Eq. (9.3) to calculate time delays. The calculated delay times can be negative or positive. This depends on the relative position of the single sites with respect to the array’s reference point and to the backazimuth of the seismic signal. Negative delay times correspond to a delay and positive delay times correspond to a signal arriving earlier than at the reference site.

Let  $w_j(\mathbf{r}_j, t)$  be the digital sample of the seismogram from site  $j$  at time  $t$ , then the beam of the whole array is defined as

$$b(t) = \frac{1}{M} \sum_{j=1}^M w_j(t + \mathbf{r}_j \cdot \mathbf{s}) = \frac{1}{M} \sum_{j=1}^M w_j(t + \tau_j). \quad (9.5)$$

This operation of summing the recordings of the  $M$  instruments by applying the time delays  $\mathbf{r} \cdot \mathbf{s}$  and then dividing by the number of traces  $M$  is called beamforming.

Because we are using digital data, sampled with a defined sampling rate, we will always need an integer number of samples in programming Eq. (9.5), that is, the term  $t + \mathbf{r}_j \cdot \mathbf{s} = t + \tau_j$  needs to be converted to an integer sample number. However, to avoid aliasing effects by following the rules of digital signal processing, it is in most cases sufficient for beamforming to use the nearest integer sample, as long as the dominant frequency is lower than ~25% of the sampling rate. If better resolution is needed one has to oversample the data. An example of the positive effects of oversampling is the beampacking algorithm (see section 9.8.2).

If seismic waves were harmonic waves  $S(t)$  without noise, with identical site responses, and without attenuation, then a “delay and sum” with Eq. (9.5) would reproduce the signal  $S(t)$  accurately. The attenuation of seismic waves within an array is usually negligible, but large amplitude differences can sometimes be observed between data from different array sites due to differences in the crust directly below the sites (see Fig. 4.34 in Chapter 4). In such cases, it can be helpful to normalize the amplitudes or to weight the traces before beamforming.

Real data  $w(t)$  are, of course, the sum of background noise  $n(t)$  plus the signal of interest  $S(t)$ , i.e.,  $w(t) = S(t) + n(t)$ .

The actual noise conditions and signal amplitude differences will influence the quality of a beam. However, the noise is usually more incoherent than the signal, i.e., signal and noise will be influenced differently by beamforming. The improvement of the signal-to-noise ratio (SNR) due to the beamforming process can be estimated as follows:

Calculating the sum of  $M$  observations and including noise we get:

$$B(t) = \sum_{j=1}^M w_j(t + \mathbf{r}_j \cdot \mathbf{s}) = \sum_{j=1}^M (S_j(t + \mathbf{r}_j \cdot \mathbf{s}) + n_j(t + \mathbf{r}_j \cdot \mathbf{s})).$$

Assuming that the signal is coherent and not attenuated, this sum can be split and we get:

$$B(t) = M \cdot S(t) + \sum_{j=1}^M n_j(t + \mathbf{r}_j \cdot \mathbf{s}). \quad (9.6)$$

Now we assume that the noise  $n_j(\mathbf{r}_j, t)$  has a normal amplitude distribution, a zero mean value, and the same variance  $\sigma^2$  at all  $M$  sites. Then, for the variance of the noise after summation, we get  $\sigma_s^2 = M \cdot \sigma^2$  and the standard deviation of the noise in the beam trace will become  $\sqrt{M} \cdot \sigma$ . That means that the standard deviation of the noise will be multiplied only with a factor of  $\sqrt{M}$ , but the coherent signal with the factor  $M$  (Eq. (9.6)). So, the theoretical improvement of the signal-to-noise ratio (SNR) by the “delay and sum” process will be  $\sqrt{M}$  for an array containing  $M$  sites. The SNR improvement, also called array gain  $G$ , of an  $M$ -sensor array can then be written as

$$G^2 = M \text{ or } G = \sqrt{M}. \quad (9.7)$$

### 9.4.6 Examples of beamforming

In the following, two examples of beamforming are shown with data from the small aperture, short-period arrays NORES and GERES. With sampling rates of 40 Hz, these arrays are optimized to observe seismic phases at regional distances. A further advantage of these arrays is the relatively large number of 25 array elements, which can theoretically give an array gain (SNR improvement) of up to  $G = 5$ .

**Fig. 9.13** Selected unfiltered NORES channels recording an event in Greece, with the beam displayed in red at top. All traces have the same amplitude scale and the unit of the time scale is in [s].

In Fig. 9.13 (top trace), we display a beam calculated by using the known apparent velocity ( $v_{app} = 10.0$  km/s) and backazimuth (BAZ =  $158^\circ$ ) for the P-onset of an event in Greece

recorded at NORES at an epicentral distance of  $21.5^\circ$ . 21 vertical sensors of the array have been used, but only the data recorded with the NORES D-ring elements are displayed together with the beam. Note that the signal on the beam is very similar to the individual signals, but the noise changes both in frequency content and amplitude level. The beam is made by calculating time delays for the given slowness and applying Eq. (9.2), and the individual traces have been shifted with these delays. There is an obvious SNR improvement (e.g., between the trace NRD8 and the beam of 2.98) but clearly less than the theoretical optimum of 4.58 times. This can have several reasons, such as:

- Non-optimum calculation of the time delay due to deviation from the assumed planar wave due to velocity anomalies below the array and along the ray path;
- The influence of lateral heterogeneities on the pulse shape of the signal at the different array sites due to multipathing, scattering or signal damping;
- Destructive interference of the noise may not work as theoretically assumed because the mean noise level at the different sites is very different;
- The noise at the different sites is not statistically independent but may have coherent components (Braun and Schweitzer, 2008).

Some approaches to further increase the SNR during beamforming of real data are described under Section 9.5.

**Fig. 9.14** Geres beam (top trace) in red for a PcP onset observed at an epicentral distance of  $9.6^\circ$  from a deep focus event in the Tyrrhenian Sea. All traces are 1 – 3 Hz bandpass filtered and have the same amplitude scale and the unit of the time scale is in [s].

The next example in Fig. 9.14 demonstrates the ability of arrays to detect small signals that are difficult to detect with single stations. It shows the tiny onset of the core reflection PcP recorded at the Geres array from a deep focus event in the Tyrrhenian Sea ( $h = 275$  km) at an epicentral distance of  $9.6^\circ$ . For the “delay and sum” process, data from 20 sites of Geres were used (with only a subset of the single traces shown). Note that although the signal coherency is low, because of the large superimposing noise amplitudes, the noise suppression on the beam is clearly visible. In this case, the SNR improvement is also less than

theoretically expected (e.g., 3.9 between GEC3 and the beam trace instead of the theoretical value of 4.5) but the onset can now be analyzed.

## 9.5 Data analysis with beamforming

### 9.5.1 The n-th root process

A non-linear method to enhance the SNR during beamforming is the so-called n-th root process (Muirhead, 1968; Kanasewich et al., 1973; Muirhead and Ram Datt, 1976). Before summing up the single seismic traces, the n-th root is calculated for each trace retaining the sign information; Eq. (9.5) then becomes:

$$B_N(t) = \frac{1}{M} \sum_{j=1}^M |w_j(t + \tau_j)|^{1/N} \cdot \text{signum}\{w_j(t)\}, \quad (9.8)$$

where the value of the function  $\text{signum}\{w_j(t)\}$  is defined as -1 or +1, depending on the sign of the actual sample  $w_j(t)$ . After this summation, the beam has to be raised to the power of  $N$ , again retaining the sign information:

$$b_N(t) = |B_N(t)|^N \cdot \text{signum}\{B_N(t)\} \quad (9.9)$$

$N$  is an integer ( $N = 2, 3, 4, \dots$ ) that has to be chosen by the analyst. The n-th root process weights the coherency of a signal higher than the amplitudes, which results in a distortion of the waveforms: the larger  $N$ , the less the original waveform of the signal is preserved. However, the suppression of uncorrelated noise is better than with linear beamforming.

### 9.5.2 Weighted stack methods

Schimmel and Paulssen (1997) introduced another non-linear stacking technique to enhance signals through reduction of incoherent noise, which shows a smaller waveform distortion than the n-th root process. In their method, the linear beam is weighted with the mean value of the so-called instantaneous phase of the actual signal. The phase term itself follows a power law, which can be defined by the analyst. With this phase-weighted stack all phase-incoherent signals will be suppressed and small coherent signals will be relatively enhanced.

Instead of the instantaneous phase, Kennett (2000) proposed the use of the semblance of the signal as a weighting function. He applied this approach not only on one (vertical) component of the observed wave field but also jointly on all three components taking into account the cross-semblance between the three components of ground movement. He achieved a resolution similar to what is achieved with the method of Schimmel and Paulssen (1997).

An easily implementable weighted stack method would be to weight the amplitudes of the single sites of an array with the SNR of the signal at this site before beamforming, but this does not directly exploit the coherency of the signals across the array. All described stacking methods can increase the slowness resolution of vespagrams (see Section 9.8.4).

### 9.5.3 The double beam technique

Spudich and Bostwick (1987) applied the principal of reciprocity and used a cluster of earthquakes as a source array to analyze coherent signals in the seismic coda. This idea was consequently expanded by Krüger et al. (1993) who analyzed seismic array data from well-known source locations (i.e., mostly explosion sources) with the so-called “double beam method”. Here the principle of reciprocity is used for source and receiver arrays to further increase the resolution and the SNR for small amplitude signals by combining both arrays in a single analysis.

### 9.5.4 Time delay corrections

Calculating time delays using  $\tau_i = \mathbf{r}_i \cdot \mathbf{s}$  is a simplification, often ignoring both elevation differences between the instruments and the fact that seismic waves are not perfect plane waves when crossing an array. To compensate for this, we have to introduce a correction  $\Delta\tau_i$ . Calculating time delays as done in Section 9.4.4 will compensate for deviations due to elevation differences (see Fig. 9.15). However, deviations from a plane wave may also be due to lateral heterogeneities below the array and if known, time corrections may improve the conformance between observed and theoretically predicted time delays.

For the large NORSAR array (NOA) e.g., elevation corrections are not used for beamforming. Instead, a database with empirical time delay corrections  $\Delta\tau_{i,l}$  was established that corrects for both elevation differences and inhomogeneities, and this database is still in use (Berteussen, 1974). So, for all beamforming, including each point in the beampacking process (see Section 9.8.2), the delays  $\Delta\tau_i$  of Eq. (9.3) are corrected according to Eq. (9.10). Note that the corrections depend on the slowness  $\mathbf{s}_l$  of the signal.

$$\tau_i = \mathbf{r}_i \cdot \mathbf{s}_l + \Delta\tau_{i,l}. \quad (9.10)$$

**Plane Wave Deviations**

**Fig. 9.15** This figure illustrates how lateral heterogeneities below an array (reddish areas) can disturb the propagation of seismic waves. Instead of a plane wave (green line on the right figure) a curved wavefront (red line) is passing the array and then (wrongly) interpreted as a plane wave (broken red line). The theoretically expected plane wave would be the green line.

A method to determine velocity heterogeneities by inverting such deviations of observed onset times from the theoretical plane wave was developed at NORSAR, the so-called ACH method (Aki, Christoffersson, and Husebye, 1977; Christoffersson and Husebye, 2011).

## 9.6 Beamforming and detection processing

A major task in processing seismic data is that of detecting possible signals in the data samples collected at the seismometers. A “signal” is defined to be distinct from the background noise due to its amplitude, different shape, and/or frequency content; in other words, the variance of the time series is increased when a signal is present. Statistically, we can form two hypotheses: the observation is noise or the observation is a signal plus noise. As aforementioned, the seismic signal observed at different sites of an array should be more coherent than random noise. If we assume that the time series recorded are independent measurements of a zero-mean Gaussian random variable, then it can be shown that the hypothesis of the recording being noise can be tested by measuring the power within a time window. If this power exceeds a preset threshold, then the hypothesis is false, i.e., the recording is signal plus noise. In practice, the threshold cannot be calculated precisely and may vary with time as is true for the background noise. An approximation to such a detector in seismology is to estimate the signal power over a long time interval (LTA = Long Term Average), and also over a short time interval (STA = Short Term (power) Average). The ratio STA/LTA, which is usually called signal-to-noise ratio (SNR), is compared with a preset threshold. If the SNR is larger than this threshold, the status of detection is set to “true” and we are speaking about a detected seismic signal.

This kind of an STA/LTA detector, proposed by Freiburger (1963), was installed and tested to our knowledge for the first time at LASA (van der Kulk et al., 1965), and later at Yellowknife (Weichert et al., 1967) and at NORSAR (Bungum et al., 1971). For complementary details on the STA/LTA trigger algorithm and its parameter settings in general, see IS 8.1. To calculate the STA, we can use a sum of the absolute values rather than the squared values (power) for computational efficiency; the difference in performance is minimal and the results are slightly more robust. The definition of the short-term average (STA) of a seismic trace  $w(t)$  is:

$$STA(t) = \frac{1}{L} \cdot \sum_{j=0}^{L-1} |w(t-j)| \quad L = \text{sampling rate} \cdot \text{STA window length}, \quad (9.11)$$

the recursive definition of the long-term average (LTA) is:

$$LTA(t) = 2^{-\zeta} \cdot STA(t-\varepsilon) + (1 - 2^{-\zeta}) \cdot LTA(t-1), \quad (9.12)$$

where  $\varepsilon$  is a time delay, typically a few seconds, and  $\zeta$  is a steering parameter for the LTA update rate. The parameter  $\varepsilon$  is needed to prevent a too early influence of the often-emergent signals on the LTA. In the case of a larger signal, the LTA may stay too long at a relatively high level and we will therefore have problems detecting smaller phases shortly after this large signal. Therefore, the LTA update is forced to lower the LTA values again by the exponent  $\zeta$ .

Then the signal-to-noise ratio (SNR) is defined as:

$$SNR(t) = STA(t)/LTA(t). \quad (9.13)$$

The STA/LTA operator may be used on any type of seismic signals or computed traces. That means, the input time series  $w(t)$  may be raw data, a beam, filtered data or a filtered beam.  $L$  is the number of points of the time series  $w(t)$  to be integrated. The recursive formulation for calculating the LTA means that the linear power estimate of the noise is based mainly on the last minute's noise situation, which is a very stable estimate. The influence of older noise conditions on the actual LTA value and a weighting of the newest STA value can be defined by the parameter  $\zeta$ , for which, e.g., at NORSAR, a value of about 6.0 is used for STA update rates of about 0.2 seconds. It is also advisable to implement a delay of  $\varepsilon = 3 - 5$  seconds for updating the LTA as compared to the STA. A simpler implementation is to estimate the LTA according to Eq. (9.11), but using an integration length that is 100 or 200 times longer for the LTA than for the STA. However, when detecting signals with frequencies above 1 Hz, it is also recommended that the LTA should not be updated while the SNR is above the detection threshold. This feature is easier to implement by using Eq. (9.12). Further details about the SNR and its improvement can be found in Section 4.4 of Chapter 4.

Figs. 9.16 and 9.17 demonstrate how the STA/LTA detector works for a single seismogram. The direct P onset of this regional event is sharp and detected clearly (Fig. 9.16). However, the P coda increases the background noise for later phases and the SNR of these phases becomes very small (Fig. 9.17). In this case, the advantages of using an array to detect seismic signals can be demonstrated easily. The apparent velocities of the P onsets and the S onsets are so different that calculating the corresponding S beam will decrease the P-phase energy and amplify the S-phase energy (Fig. 9.18).

**Fig. 9.16** LTA, STA and STA/LTA (= SNR) traces for a seismogram of a regional event observed at the ARCES reference site ARA0 (bottom). The seismogram was bandpass filtered between 4 and 8 Hz. Note the sharp onset for the P phase with an SNR of 108.175.

**Fig. 9.17** As Fig. 9.16, but only for the time window after the P onset. Note that due to the P coda the noise and consequently the LTA is increased. Therefore the SNR of the S-phase onsets becomes relatively small on this single vertical trace.

**Fig. 9.18** As Fig. 9.17, but with LTA, STA and SNR calculated for a beam optimized for the first S onset. The array beam is shown as the second trace from the bottom. Compare the relative amplitudes of the P-coda on the array beam and on the single station seismogram at ARA0, which is shown at the bottom (note the different scaling factors to the left of the traces).

In Fig. 9.19 we display again the Greek event from Fig. 9.13 with the “best” beam ( $v_{app} = 10.0$  km/s, backazimuth  $158^\circ$ ) on top, together with beams using the same apparent velocity of 10.0 km/s but different backazimuths ( $0.0^\circ$ ,  $90.0^\circ$ ,  $180.0^\circ$  and  $270.0^\circ$ ). Note the difference in amplitudes of the beams for signal and noise. Because the “best” backazimuth of  $158^\circ$  is relatively close to  $180.0^\circ$ , the top trace and the second trace from the bottom differ only slightly. Thus, Fig. 9.19 demonstrates **resolution limits** for small aperture arrays like NORES. To find the “best” beam is, in principle, a matter of forming beams with different slowness vectors and comparing the amplitudes or the power of the beams, and then finding which  $v_{app}$ -backazimuth combination gives the highest signal energy on the beam.

**Fig. 9.19** NORES beams for the same event as in Fig. 9.13 with different slownesses. At top we plot again the best beam of Fig. 9.13. The other four traces are NORES beams of the same data now calculated by applying a constant apparent velocity of 10 km/s and different backazimuths (BAZ). The traces are unfiltered and are plotted with an equal amplitude scale.

In Fig. 9.20, the same beams as in Fig. 9.19 are shown, but now filtered using a Butterworth 3rd order bandpass filter between 2 and 4 Hz. When beamforming using Eq. (9.5), we can either filter all the individual traces first and then beamform, or we can beamform first, and then filter the beam, which is faster by a factor of the number of sites minus one. Both procedures should theoretically give the same result because both beamforming and filtering are linear processes. However, locally increased noise levels at single sites can make it useful to filter the single traces first to avoid leakage of low frequency energy when using tools containing Fourier analysis applications.

**Fig. 9.20** This figure shows the same beams as in Fig. 9.19 but filtered with a Butterworth bandpass filter between 2 and 4 Hz. All traces have an equal amplitude scale.

**Fig. 9.21** Illustration of an incoherent beam (see text) which is shown on top in red. The other traces are STA time series. The selected NORES channels have been pre-filtered with a Butterworth bandpass filter between 2 and 4 Hz. All traces have an equal amplitude scale.

Fig. 9.21 (top trace) shows an incoherent beam, made by first filtering the raw data, then computing STA time series of each trace and afterwards, summing up the STA traces. The STA traces can be time shifted using time delays for a given slowness vector, but for detection purposes, when using a small aperture array, this is not necessary since the time shifts will be very small compared to the envelope of the signal. An incoherent beam will reduce the noise variance and can be used to detect signals that are incoherent across an array. Such incoherent signals are typically of higher frequency. When calculating incoherent beams, filtering must (!) be the first step.

## 9.7 Array transfer function

The array transfer function describes sensitivity and resolution of an array for seismic signals with different frequency contents and slownesses. When digitizing the output from a seismometer, we are sampling a seismic signal in the time domain, and to avoid aliasing effects, we need to apply an anti-aliasing filter. Similarly, when observing the wavefront of a seismic signal using an array, we obtain a spatial sampling of the ground movement. With an array, or a dense network, we are able to observe the wavenumber  $k = 2\pi/\lambda = 2\pi \cdot f \cdot s$  of this wave defined by its wavelength  $\lambda$  (or frequency  $f$ ) and its slowness  $s$ . While analog-to-digital conversion may give aliasing effects in the time domain, the spatial sampling may give aliasing effects in the wavenumber domain. Therefore the wavelength range of seismic signals, which can be investigated, and the sensitivity at different wavelengths must be estimated for a given array.

A large volume of literature exists on the theory of array characteristics, e.g., Barber (1958; 1959), Somers and Manchee (1966), Haubrich (1968), Doornbos and Husebye (1972), Harjes and Henger (1973), Harjes and Seidl (1978), Mykkeltveit et al. (1983; 1988), Johnson and Dudgeon (1993; 2002), Harjes (1990), and Wang (2002), but array theory can also be found in seismological textbooks (e.g., Capon, 1973; Aki and Richards, 1980; Bullen and Bolt, 1985; Buttkus, 2000; Kennett, 2002). We will describe in the following how the array transfer function can be estimated.

Assuming a noise and attenuation free plane-wave signal, the difference between a signal  $w$  at the reference site  $A$  and the signal  $w_n$  at any other sensor  $A_n$  is only the travel time between the arrivals at the sensors. As we know from Section 9.4, a plane wave is defined by its propagation direction and its apparent velocity, or in short by its slowness vector  $\mathbf{s}_o$ . Thus we can write:

$$w_n(t) = w(t - \mathbf{r}_n \cdot \mathbf{s}_o) .$$

Following Eq. (9.5) the best beam of an array with  $M$  sensors for a seismic signal for the slowness  $\mathbf{s}_o$  is defined as

$$b(t) = \frac{1}{M} \sum_{j=1}^M w_j(t + \mathbf{r}_j \cdot \mathbf{s}_o) = w(t) . \quad (9.14)$$

The seismic signal at sensor  $A_n$  of a plane wave for any other slowness  $\mathbf{s}$  can be written as  $w_n(t) = w(t - \mathbf{r}_n \cdot \mathbf{s})$  and the beam is given by

$$b(t) = \frac{1}{M} \sum_{j=1}^M w_j(t + \mathbf{r}_j \cdot \mathbf{s}). \quad (9.15)$$

If we calculate all time shifts for a signal with the (correct) slowness  $\mathbf{s}_o$  (Eq. (9.14)) with respect to any other slowness  $\mathbf{s}$  (Eq. (9.15)), we get the difference for the signal at site  $A_n$   $w(t + \mathbf{r}_n \cdot \mathbf{s}_o - \mathbf{r}_n \cdot \mathbf{s}) = w(t + \mathbf{r}_n \cdot (\mathbf{s}_o - \mathbf{s}))$ . The calculated beam can be written as

$$b(t) = \frac{1}{M} \sum_{j=1}^M w_j(t + \mathbf{r}_j \cdot (\mathbf{s}_o - \mathbf{s})). \quad (9.16)$$

This beam is now a function of the difference between the two slowness values  $(\mathbf{s}_o - \mathbf{s})$  and the geometry of the array  $\mathbf{r}_j$ . If the correct slowness is used, the beam calculated with Eq. (9.16) will be identical to the original signal  $w(t)$ . The seismic energy of this beam can be calculated by integrating over the squared amplitudes:

$$E(t) = \int_{-\infty}^{\infty} b^2(t) dt = \int_{-\infty}^{\infty} \left[ \frac{1}{M} \sum_{j=1}^M w_j(t + \mathbf{r}_j \cdot (\mathbf{s}_o - \mathbf{s})) \right]^2 dt. \quad (9.17)$$

This equation can be written in the frequency domain by applying Parseval's theorem and then the shifting theorem:

$$E(\omega, \mathbf{s}_o - \mathbf{s}) = \frac{1}{2\pi} \int_{-\infty}^{\infty} |\bar{w}(\omega)|^2 \cdot \left| \frac{1}{M} \sum_{j=1}^M e^{i\omega \mathbf{r}_j \cdot (\mathbf{s}_o - \mathbf{s})} \right|^2 d\omega \quad (9.18)$$

with  $\bar{w}(\omega)$  being the Fourier transform of the seismogram  $w(t)$ . Using the definition of the wavenumber vector  $\mathbf{k} = \omega \cdot \mathbf{s}$ , we can also write  $\mathbf{k}_o = \omega \cdot \mathbf{s}_o$ :

$$E(\omega, \mathbf{k}_o - \mathbf{k}) = \frac{1}{2\pi} \int_{-\infty}^{\infty} |\bar{w}(\omega)|^2 \cdot |C(\mathbf{k}_o - \mathbf{k})|^2 d\omega, \text{ where} \quad (9.19)$$

$$|C(\mathbf{k}_o - \mathbf{k})|^2 = \left| \frac{1}{M} \sum_{j=1}^M e^{i\omega \mathbf{r}_j \cdot (\mathbf{k}_o - \mathbf{k})} \right|^2. \quad (9.20)$$

Eq. (9.18) or Eq. (9.19) defines the energy of an array beam for a plane wave with the slowness  $\mathbf{s}_o$  (or  $\mathbf{k}_o$ ), but calculating the applied time shifts for a slowness  $\mathbf{s}$  (or  $\mathbf{k}$ ). If the difference between  $\mathbf{s}_o$  and  $\mathbf{s}$  (or  $\mathbf{k}_o$  and  $\mathbf{k}$ ) changes, the resulting beam has a different energy. However, this dependency is not a function of the actual signals observed at the single sites, but only a function of the array geometry weighted with the slowness difference  $\mathbf{r}_n \cdot (\mathbf{k}_o - \mathbf{k})$  (Eq. (9.19)). If the slowness difference is zero, the factor  $|C(\mathbf{k}_o - \mathbf{k})|^2$  becomes 1.0 and the array is optimally tuned for this slowness. All other energy propagating with a different slowness will be (partly) suppressed. Therefore, Eq. (9.20) is called the transfer function of an array. This function is not only dependent on the slowness of the seismic phase observed with the array, but also on the frequency, i.e., a function of the wavenumber  $k$  of the observed signal, and of the array geometry.

There exists literature about general criteria used to evaluate array transfer functions for a given array geometry (see e.g., Harjes and Henger, 1973; Johnson and Dudgeon 1993; 2002). Some general rules about transfer characteristics of arrays can be formulated as follows:

- 1) The aperture of an array defines the resolution of the array for small wavenumbers. The larger the aperture  $a$ , the smaller are the wavenumbers that can be measured with the array. The upper limit for the longest wavelength  $\lambda$  that can be resolved by array techniques is approximately similar to the aperture  $a$  of the array. The array behaves like a single station for signals with  $\lambda \gg a$ .
- 2) The number of sites controls the quality of the array as a wavenumber filter, i.e., its ability to suppress seismic energy crossing simultaneously with a different slowness the array than the one on which the array is steered. (see point 4).
- 3) The distances between the seismometers define the position of the side lobes of the array transfer function and the largest resolvable wavenumber: the smaller the mean distance, the smaller the wavelength of a resolvable seismic phase will be (for a given seismic velocity).
- 4) The geometry of the array defines the azimuth dependence of the aforementioned points.

Some of these points are demonstrated by two examples of array transfer functions. Fig. 9.22 shows the array transfer function of the cross-shaped Yellowknife array (YKA, see Fig. 9.1) and Fig. 9.23 shows the array transfer function of the circular, small aperture array ARCES.

**Fig. 9.22** This figure shows the array transfer function of the cross-shaped Yellowknife array (see Fig. 9.1) as relative power (color coded and with white isolines) of the array response normalized with its maximum.

**Fig. 9.23** This figure illustrates the array transfer function of the circular ARCES array (see Fig. 9.3). The figure shows relative power of the array response normalized with its maximum. White isolines were plotted at -1, -3, -5, -7, and -9 db below the maximum of the array response.

The ARCES geometry (see Fig. 9.3) gives a perfect azimuthal resolution, and the side lobes of the transfer function are far away from the main lobe. However, because of the small aperture, this array cannot distinguish between waves with small wavenumber differences, as can be seen in the relatively wide main lobe of the transfer function. In contrast, in the case of Yellowknife, the main lobe is very narrow because of the much larger aperture of the array. This results in a higher resolution in measuring apparent velocities. But the array shows resolution differences for different azimuths, which are caused by its geometry. The many side lobes of the transfer function are the effect of the larger distances between the single array sites.

Details on array design for the purpose of maximizing the gain achievable by beamforming can be found in Section 9.11.

## 9.8 Slowness estimation using seismic arrays

In the following sections we will introduce the “f-k analysis” and “beampacking” methods. Simply speaking, it is all a matter of forming beams with different slowness vectors and comparing the amplitudes or the power of the beams, and then finding out which  $v_{app}$  – backazimuth combination gives the highest energy on the beam, i.e., to find out which beam

is the “best” beam. In f-k analysis the process is done in the frequency domain rather than in the time domain. Both methods are nowadays the theoretical background for many different approaches not only in global and regional array seismology but also in local velocity structure and site effect investigations (see also Chapter 13, Section 13.4.4 and Chapter 14, Section 14.3.2.1).

### 9.8.1 Slowness estimation by f-k analysis

Frequency-wavenumber analysis – “f-k analysis” – is used as a reference tool in array processing for estimating slowness. A description of the method may be found, e.g., in Capon (1969a) or as a larger review in Capon (1973). This method has been further developed to include wide-band analysis, maximum-likelihood estimation techniques, and three-component data (Kværna and Doornbos, 1986; Kværna and Ringdal, 1986; Ødegaard et al., 1990). Theoretical aspects and information on the development of the methodology are also found in several textbooks on seismology and geophysics (Capon, 1973; Aki and Richards, 1980; Buttkus, 2000; Kennett, 2002), as well as in numerous original articles or review papers since the 1960s (e.g., Burg, 1964; Lacoss, 1965; Linville and Laster, 1966; Iyer, 1968; Liaw and McEvelly, 1979; Rost and Thomas, 2002).

The methodology exploits the deterministic, non-periodic character of seismic wave propagation to calculate the frequency-wavenumber spectrum of the signals by applying the multidimensional Fourier transform. Under these assumptions, a monochromatic, plane wave  $w(x,t)$  will propagate along the  $x$  direction according to equation:

$$w(x,t) = Ae^{i2\pi(f_0t - k_0x)}, \quad (9.21)$$

where  $A$  is the amplitude,  $f_0$  the frequency and  $k_0$  the wavenumber in the  $x$  direction. Application of the two-dimensional Fourier transform provides:

$$W(k_x, f) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} Ae^{-i2\pi[t(f-f_0) - x(k_x-k_0)]} dx dt. \quad (9.22)$$

Using the delta function properties, Eq. (9.22) can be rewritten as follows:

$$W(k_x, f) = A\delta(f - f_0)\delta(k_x - k_0). \quad (9.23)$$

Eq. (9.23) suggests the possibility to map a plane, monochromatic wave in the frequency-wavenumber domain as a point, with coordinates  $(f, k_x) = (f_0, k_0)$ , which are nothing else than the frequency and wavenumber of the wave (e.g., Buttkus, 2000). Since the velocity of this wave is related to its wavenumber through the expression  $v_0 = \frac{f_0}{k_0}$ , it is easy to observe that

the wave’s velocity is the slope of the line connecting the point  $(f_0, k_0)$  in the frequency-wavenumber domain with the origin of the applied coordinate system  $f, k_x$ .

**Fig. 9.24** Frequency-slowness distribution of different types of waves: surface waves, body waves and coherent noise (slight modification of Fig. 7.3 from Buttkus, 2000, p. 107).

**Fig. 9.25** NORES recordings (raw data) of the Lop Nor explosion on May 15, 1995. Traces from the center site A0 and the D-ring instruments are shown to the same scale. The time scale is in [s].

Transferring our observations onto the  $k_x k_y$  plane, the angle between the  $k_y$  axis and the direction to the point  $(f_0, k_0)$  is the azimuth of the wave under discussion. Thus, measuring waves in two-dimensions, which we place on the Earth's surface, and assuming that  $k_x, k_y$  are

the wavenumber along the  $x$  and  $y$  direction respectively, provides us through f-k analysis with  $f$ ,  $k_x$ ,  $k_y$  and thereby the slowness distribution of the different types of signals. Adding frequency as a third dimension results in the formation of a ‘cone’, as in Fig. 9.24, where the different types of waves (i.e., body and surface waves, coherent noise) occupy specific concentric areas which in most cases do not overlap. In reality, the spectrum of seismic signals in its entirety exhibits a much larger complexity than the simplistic approach shown in Fig. 9.24. This is the result of a large number of factors affecting seismic signals, such as the geometry of near-surface crustal structure, the inhomogeneity of the crust, topography, etc., to mention only a few.

Practically, f-k analysis is performed in the frequency domain and represents in principle beamforming in the frequency domain for a number of different slowness values. A time shift in the time domain is equivalent to a phase shift in the frequency domain, since time is the analogue to angular frequency and space the analogue to wavenumber. Normally, at NORSAR we use slowness values between -0.4 and 0.4 s/km equally spaced over 51 by 51 points. For every one of these points the beam power is evaluated, giving an equally spaced grid of 2601 points with power information.

Such a power grid is displayed in Fig. 9.26 with the slowness ranging from -0.2 to 0.2 s/km; the unfiltered data are shown in Fig. 9.25. The power is displayed by isolines of dB down from the maximum power. The maximum power in the grid and the corresponding slowness vector define the slowness of the plane wave.

**Fig. 9.26** Result from wide-band f-k analysis of NORES data from a 3 second window around the signal shown in Fig. 9.25. The isolines are in dB from the maximum peak and the color-coded relative power is a measure of signal coherency.

In the f-k plot in Fig. 9.26 color-coding is used to represent the relative power of the multichannel signal for 51 by 51 points in slowness space. Because the f-k analysis is a frequency-domain method, one has to define a frequency range of interest. In our case the data were analyzed in the frequency range between 1.2 and 3.2 Hz. The peak level is found at an apparent velocity of 20.3 km/s and a backazimuth of 83.4°. The normalized relative peak power is 0.96. This measure tells us how coherent the signal is between the different sites and that a beam formed with the corresponding slowness will give a signal power that is 0.96 times the average power of the individual sensors. This means that the estimated beam signal will have practically no signal loss for this slowness and in this filter band as compared to individual sensors. However, such beam loss can be taken into account when calculating station magnitudes by adding empirically derived corrections. The equivalent beam total power in Fig. 9.26 is 84.22 dB. The isolines tell us that using any different (i.e., wrong) slowness will give a signal loss of maximum 10 dB, which would correspond to an underestimation of magnitude by 0.5 magnitude units, if uncorrected.

The example in Fig. 9.26 is in a way a cross-section of the cone of Fig. 9.24 for the frequency interval 1.2 to 3.2 Hz, “focused” on the characteristics of the seismic phase selected for analysis. As already mentioned in Section 9.7, the shape of the horizontal slowness distribution is defined by the position of the elements of the recording array and the distances between them.

An uncertainty of the estimated apparent velocity and backazimuth can be derived from the size of the observed power maximum in the f-k plot at a given dB level below the maximum, the SNR of the signal, and the power difference between the maximum and any existing secondary maximum that may be present in the plot.

Fig. 9.27 displays the f-k analysis results for a 1.5 s long window of a signal arriving vertically at the array displayed at the bottom, for a narrow (left) and a wide (right) frequency range. The strong side-lobes appearing in the case when the technique is applied to a narrow frequency band ( $6.0 \pm 0.1$  Hz) are eliminated by the application over a wider range (1.9 – 10.0 Hz). Kværna and Doornbos (1986) reported on f-k analysis techniques using an integration over a wider frequency band (also called “wide-band” or “broadband” f-k analysis) rather than the single frequency-wavenumber analysis (e.g., Capon, 1969a; 1973) as applied by many authors. Fig. 9.27 demonstrates the increased stability of the wide-band f-k analysis (Kværna and Doornbos, 1986; Kværna and Ringdal, 1986) for data of adequately high SNR over the selected frequency range. The reason for this is that the positions of the side-lobes in the f-k space are frequency dependent. To the contrary, the main-lobe for different frequencies is always positioned at the same place. So, summing up f-k results for different frequencies increases the amplitude distance between the main and the side-lobes.

The result of an f-k analysis also depends on the method employed to determine the maximum power in the grid. There exists a variety of methods, such as the maximum likelihood method (Kelly and Levin, 1964; Levin, 1964; Capon et al., 1967), the maximum entropy method (Burg, 1967), the multiple signal classification (MUSIC) algorithm (Schmidt, 1986) and various adaptive algorithms for the estimation of spectral power density (e.g., Goldstein and Archuleta, 1991a; Goldstein and Chouet, 1994; Fujiwara, 1997).

**Fig. 9.27** Results from narrow- (upper left) and wide-band (upper right) f-k analysis of a 1.5 second window of a signal arriving vertically at the seismic array shown below. The narrow frequency band extends from 5.9 to 6.1 Hz, while wide-band f-k analysis was applied over the range 1.9 – 10.0 Hz. The isolines are in dB from the maximum peak and the color-coded relative power is a measure of signal coherency. The black circles represent apparent velocities of 8, 6 and 3 km/s, respectively.

### 9.8.2 Beampacking (time domain wavenumber analysis)

An alternative to the technique described above is the so-called beampacking scheme, which had been developed at NORSAR to apply f-k analysis of regional phases to data of the large NORSAR array (NOA). This algorithm performs in the time domain beamforming over a predefined grid of slowness points and measures the power of the beam.

As an example see Fig. 9.28, where we used the same NORES data as for the f-k analysis in Fig. 9.26. All data were prefiltered with a Butterworth 1.2 – 3.2 Hz bandpass filter to make the results comparable with the f-k result in Fig. 9.26. To obtain a similar resolution as for the f-k analysis, the time domain wavenumber analysis requires a relatively high sample rate of the data. Therefore, we oversampled the data in this example 5 times by interpolation, i.e., we changed the sample rate from 40 to 200 Hz.

One can see from the beampacking process that we get practically the same slowness estimate as for the f-k analysis in the frequency domain (Fig. 9.26). In the time domain case, the relative power is the signal power of the beam for the peak slowness divided by the average sensor power in the same time window. The total power of 91.45 dB in Fig. 9.28 is the maximum beam power.

Compared to the f-k process used, the resulting total power is now 6 dB higher, which is due to the measurement method, and not a real gain. However, the beampacking process results in a slightly (about 10%) narrower peak for the maximum power as compared with f-k analysis.

**Fig. 9.28** Result from beampacking of the NORES data in Fig. 9.27 in an equispaced slowness grid. The data were prefiltered in the band 1.2 – 3.2 Hz and were resampled to 200 Hz. The isolines represent power of each beam within the 3-second window analyzed.

### 9.8.3 Plane wave fitting – slowness estimation by time picks

Yet another way of estimating slowness is to pick carefully times of the first onset or any other common distinguishable part of the same phase (same cycle) for all instruments in an array (see Fig. 9.29). Estimating the ray parameter and BAZ of a teleseismic P onset by fitting an assumed plane wave to a set of onset times was first applied by Abt (1907). Today, we may, e.g., use Eq. (9.24) to estimate the slowness vector  $\mathbf{s}$  by a least squares fit to the observations.

Let  $t_i$  be the arrival time picked at site  $i$ , and  $t_{ref}$  be the arrival time at the reference site, then  $\tau_i = t_i - t_{ref}$  is the observed time delay at site  $i$ . We observe the plane wave at  $M$  sites. With  $M \geq 3$ , we can estimate the horizontal components ( $s_x, s_y$ ) of the slowness vector  $\mathbf{s}$  by using e.g., a least squares fitting algorithm. If  $M \geq 4$ , the vertical component of the slowness vector ( $s_z$ ) can also be resolved. The uncertainties of the estimated parameters can be calculated simultaneously by solving the equation system of Eq. (9.24).

$$\sum_{i=1}^M (\tau_i - \mathbf{r}_i \cdot \mathbf{s})^2 = \min . \quad (9.24)$$

This method requires interactive analyst work. However, to obtain automatic time picks and thereby provide a slowness estimate automatically, techniques like cross-correlation (matched filtering) or just picking of peak amplitude within a time window (for phases that have an impulsive onset and last two or three cycles) may be used (see e.g., Del Pezzo and Giudicepietro, 2002).

**Fig. 9.29** NOA recording of the Lop Nor explosion of May 15, 1995. Vertical traces (sz) from the sites 02B0, 01B5, 02C4, and 04C5 of the NOA array (see also Fig. 9.2) are shown at the same amplitude scale. Note the large time delays as compared to the smaller NORES array in Fig. 9.27. The figure illustrates a simple time pick procedure of the individual onsets. A plane wave fit to these 4 onset-time measurements gives a backazimuth of  $77.5^\circ$  (theoretically expected  $76.1^\circ$ ) and an apparent velocity of 16.3 km/s, which is close to the theoretical value of 14.5 km/s corresponding to an epicentral distance of  $61^\circ$ .

The so-called Progressive Multichannel Cross Correlation (P.M.C.C) program package can apply inter-sensor correlation functions between single array traces to estimate BAZ and slowness of seismic signals in a continuous mode (see Cansi et al., 1993; Cansi, 1995). However, because of the amount of required computations, this method is most effective for arrays with a smaller number of sites or for subarray configurations.

#### 9.8.4 The VESPA algorithm

A method to separate signals propagating with different apparent velocities is the VElocity SPectrum Analysis (VESPA). The principal idea of this method is to estimate the seismic energy reaching an array with different slownesses and to plot the beam energy along the time

axis. The usual way to display a vespagram is to calculate the observed energy for specific beams and to construct an isoline plot of the observed energy for the different slowness values. The original VESPA process was defined for plotting the observed energy from a specific azimuth for different apparent velocities versus time (Davies et al., 1971).

Fig. 9.30 shows as an example of a vespagram for a mine blast in the Khibiny Massif (Kola Peninsula) observed with the ARCES array. The underground blasting of about 190 tons of explosives occurred on December 21, 1992 at 07:10 (latitude 67.67°, longitude 33.73°) at about 3.55° epicentral distance from ARCES. All beams were calculated with the theoretical backazimuth of 118°, and the seismograms were bandpass filtered between 2 and 8 Hz. Fig 9.30 (middle) shows two of the filtered seismograms used to calculate the vespagram.

**Fig. 9.30** Vespagram for a mining explosion (December 21, 1992; 07:10 h; latitude 67.67° N, longitude 33.73° E) in the Khibiny Massif observed at ARCES. Shown is the observed seismic energy for different apparent velocities (slownesses) and a constant backazimuth of 118°.

The energy for the different slowness values was calculated for 3 second-long sliding windows moved forward in 0.5 s long steps. The observed energy was normalized with the maximum value and the isolines were plotted as contour lines in [dB] below this maximum. Note that the first two P onsets both have a slowness of about 0.125 s/km equivalent to an apparent velocity of 8 km/s; these are the Pn phase and a superposition of onsets from several crustal phases. The S phases are clearly separated from the P phases in the slowness space; Sn with a slowness of about 0.225 s/km (corresponding to an apparent velocity of about 4.44 km/s) and the dominating Lg phase with a slowness of about 0.28 s/km or an apparent velocity of about 3.57 km/s.

Later, the vespagram concept was expanded by plotting the observed energy from different azimuths using a specific apparent velocity. Fig. 9.31 shows an example for such a plot for the same event in the Khibiny Massif as for Fig. 9.30.

**Fig. 9.31** As Fig. 9.30 but the energy is now calculated for a constant apparent velocity of 8 km/s (i.e., a slowness of 0.125 s/km) and different backazimuths.

Instead of a constant backazimuth, a constant apparent velocity of 8 km/s was used to calculate the beam energy from all azimuth directions. Note also that the noise preceding the first P onset contains energy with apparent velocities around 8 km/s, but this noise approaches the array from a different backazimuth ( $310^\circ$ ), and the crustal P phases show a slight shift in the backazimuth direction relative to the first mantle P phase ( $P_n$ ).

### **9.8.5 The correlation method used at the UKAEA arrays**

As discussed in Section 9.7, the array transfer function of the UKAEA array YKA shows strong side lobes along a rectangular grid (see Fig. 9.21). This effect can be observed at all orthogonal linear or L-shaped arrays (Birtill and Whiteway, 1965). To improve the lower resolution along these principal axes, a correlation method has been introduced. In a first step, theoretical beams are calculated separately for each of the two seismometer lines; the geometrical crossing point of the two linear subarrays is used as the common reference point for both beams. If the actual signal has the same slowness as the slowness used to calculate the two beams, the signal must be in phase on both beams. In a second step, the calculation of the cross-correlation between the two beams tests this condition. The correlator trace is calculated for a short, moving time window. This non-linear process is very sensitive to small phase differences and improves the resolution of such arrays especially along the principal axes of their transfer functions (for further details see Whiteway, 1965; Birtill and Whiteway, 1965; Weichert et al., 1967).

### **9.8.6 Tracking earthquake source propagation with seismic arrays**

Usually earthquakes are modeled as point sources. The hypocenter of an earthquake is defined as the point where the initial rupture starts (see IS 11.1). However, for many studies the geometry of the rupture and its dynamics are of importance. Spudich and Cranswick (1984) published a study, in which they used data from a small linear accelerometer array to investigate the dynamics of the 1979 Imperial Valley, California earthquake. Similar studies were made by Goldstein and Archuleta (1991b) and Huang (2001), who used data from two very small aperture accelerometer arrays in Taiwan (SMART-1 (Abrahamson et al., 1987) and SMART-2 (Chiu et al., 1994)) to investigate rupture propagation of large Taiwan earthquakes. Common for these studies is that they all applied array analysis techniques to strong motion data from nearby strong earthquakes.

After the huge 2004 Sumatra earthquake, a slightly different approach was tested and implemented. The fault length of this event was more than 1000 km long and using data from the German network of broadband stations or the Japanese Hi-Net array, the rupture propagation of this earthquake could be monitored at teleseismic distances by applying array techniques (Krüger and Ohrnberger, 2005a and b; Ishii et al., 2005a and b). These authors measured BAZ and slowness in a moving window for times after the direct first P onset. Usually, one can observe the different seismic phases (see e.g., the VESPA algorithm in Section 9.8.4) arriving at the array. In the case of very large arrays, however, the seismograms during these time windows are dominated by the seismic energy radiated during the ongoing source process itself. The authors could show that the observed systematic change of BAZ and slowness can only be explained by the continuous seismic energy radiating rupture along the seismic fault. Later, several authors applied this technique to investigate rupture dynamics

of large earthquakes and today even an automated version for continuous monitoring of megathrust zones has been tested (Roessler et al., 2010).

### 9.8.7 Slowness corrections

When observing the backazimuth of an approaching wave, we find deviations from the expected backazimuth. In addition, the observed ray parameter will also be different from the theoretical one. This observation is valid for any seismic station. If the deviation is systematic and consistent for a given source location (or small region), we can correct for this deviation. If the predicted slowness is  $s_c$  and the observed slowness is  $s_o$  (Fig. 9.32), then the slowness deviation is

$$\Delta s = s_o - s_c. \quad (9.25)$$

It is also common to use the ray parameter  $p$  [ $s/^\circ$ ] and the backazimuth  $BAZ$  [ $^\circ$ ] as slowness vector components and to express the residuals as:

$$\Delta p = p_o - p_c \text{ and } \Delta BAZ = BAZ_o - BAZ_c. \quad (9.26)$$

However, every array has to be calibrated with its own corrections. Numerous studies have been performed to obtain slowness corrections for different seismic arrays (see e.g., Berteussen, 1976; Krüger and Weber, 1992; Bondár et al., 1999; Kuleli et al., 2001; Schweitzer, 2001; and more recent examples of such studies are, e.g., Hao and Zheng, 2009; Tibuleac and Stroujkova, 2009; or Shen and Ritter, 2010). Usually, the derivation of slowness corrections for the whole slowness range observable with one array needs a large amount of corresponding reference data and therefore takes some time.

**Fig. 9.32** Slowness vector deviation in the horizontal plane. The vector  $s_c$  denotes the theoretical slowness. The vector  $s_o$  denotes the observed slowness. The vector  $\Delta s$  denotes the slowness residual, also referred to as the mislocation vector. The length of the slowness vector measured in [ $s/^\circ$ ] is the ray parameter  $p$ , and the angle between North and the slowness vector, measured clockwise, is the backazimuth  $BAZ$ .

## 9.9 Detection of repeating seismic events using waveform cross-correlation

In the same way that signals generated by a seismic event will resemble each other on two sensors with a sufficiently small separation, signals generated by two different seismic events will show similarity on a given sensor provided that the spatial separation of the event source locations is sufficiently small and that the event mechanisms are similar (see e.g., Geller and Mueller, 1980). This is to say that the signal observed at any seismic station is like a fingerprint for events within a given limited geographical region, as long as the seismic wave radiation pattern does not change. The degree of similarity between two segments of waveform can be measured by calculating their cross-correlation coefficient (CC). Given a signal template from a previously observed event, subsequent occurrences of that signal can be detected by calculating a continuous cross-correlation trace on the incoming data stream at the same site.

**Fig. 9.33** Illustration of detection by waveform correlation on the ARCES array of an earthquake in April 2008 using a template from an event in 2007 as a master signal (from Bungum et al., 2010). All waveforms were bandpass filtered between 2 and 8 Hz prior to performing the cross-correlation.

The principle is illustrated in Fig. 9.33. A signal template is extracted on the ARCES array for a shallow earthquake in the Steigen region of northern Norway at an epicentral distance of approximately 460 km. This template is correlated with successive segments of data and the occurrences of new earthquakes close to the site of the master event are detected by identifying times, at which the correlation coefficient is sufficiently greater than the

background level. A second peak is observed in the correlation coefficient trace approximately two minutes after the first. This indicates the presence of an aftershock whose signal is buried in the coda of the first event. This processing is done for all available array traces. If a seismic signal is present, all correlation coefficient traces should have a maximum at the same time and one can stack the correlation coefficient traces without any time delay application. The SNR on the summed correlation coefficient trace will be increased and even tiny signals hidden in the noise or other signals can be detected.

Gibbons and Ringdal (2006) describe a number of applications of the method and point out that, especially on small-aperture arrays, false alarms can occur due to a coincidental waveform similarity over a short time window. Such false detections can frequently be identified by examining the alignment of the correlation coefficient traces on the single sensors. In the case of small-aperture arrays, Gibbons and Ringdal (2006) demonstrate that the correlation traces emulate a wavefront that propagates over the array with an apparent slowness vector which is approximately equal to the difference between the dominant slowness vectors of the master and detected events. If performing wide-band f-k analysis on the cross-correlation (CC) traces indicates a non-zero slowness vector then the detected signal cannot arrive from the same direction as the master event signal and the detection can be classified automatically as a false alarm and ignored. Fig. 9.34 displays the alignment of single channel CC-traces at ARCES for the Steigen event in Fig. 9.33 together with the slowness grid from the f-k analysis.

**Fig. 9.34** Verification of the validity of a cross-correlation detection by performing f-k analysis on the individual correlation coefficient traces. A non-zero slowness vector would indicate that the signals from the master and detected events do not come from the same direction.

## 9.10 Ambient noise array analysis

### 9.10.1. Overview

During the last decades, ambient seismic vibration measurements have gained in importance, especially in regions covered with soft sediments (e.g., Aki, 1957; Horike, 1985; Tokimatsu, 1997; Okada, 2003; Foti et al., 2011). Advantages of the method are its low cost as well as the non-destructivity of measurements and thus its applicability even in densely populated areas. Whereas the presence of strong seismic noise is obstructive for active seismic investigations, it constitutes a continuous energy source for ambient seismic vibration measurements illuminating the subsurface.

One widespread application of ambient vibration measurements are microzonation studies (single station measurements analyzed with the H/V method, see e.g., Tokimatsu, 1997). Later on, the H/V method emerged as a geophysical tool to assess soil and sedimentary thickness, the analyzed depth ranging from tens of meters to more than 1000 m (e.g., Ibs von Seht and Wohlenberger, 1999; Delgado et al., 2000; Parolai et al., 2001). The H/V spectrum has even been employed to gain shear wave velocity profiles (Fäh et al., 2003; Parolai et al., 2002; Arai and Tokimatsu, 2004), but usually, ambient vibration array measurements are used to estimate the shear wave velocity structure (e.g., Asten and Henstridge, 1984; Horike, 1985; Tokimatsu, 1997; Scherbaum et al., 2003). However, the trade-off between accumulated travel times in the sediment structure and depth of the main impedance contrasts led to the development of combined inversion strategies from both techniques (Scherbaum et al., 2003; Parolai et al., 2005; Picozzi et al., 2005). A set of useful guidelines for single station and array measurements of ambient seismic vibrations was developed within the framework of the EU-project SESAME (Site Effects uSing AMbient Excitations, see e.g., SESAME group, 2004; Jongmans et al., 2005). For more details about the investigation of site response in urban areas by using earthquake data or seismic noise see Chapter 14.

A detailed review of sources of ambient vibrations can be found in Section 4.3 in Chapter 4. A discussion of noise which is specifically related to ambient vibration analysis is given in Bonnefoy-Claudet et al. (2004). At low frequencies (below 1 Hz), ambient vibrations seem to mainly consist of fundamental Rayleigh waves mostly caused by meteorological phenomena. However, at higher frequencies the noise sources are mostly caused by human activities and there is no agreement yet between authors on the ratio between body and surface waves as well as the ratio between Love and Rayleigh waves and fundamental and higher modes.

### 9.10.2 Single station/array measurements

Single station H/V analysis techniques (also known as Nakamura's technique, see Nogoshi and Igarashi, 1971; Nakamura, 1989; Bard, 1999) analyze ambient vibrations measured on horizontal and vertical seismometer components to estimate the fundamental resonance period of high impedance sediment layers overlaid by lower impedance materials (e.g., sediment over bedrock). The fundamental period is derived from the observation of a peak in the H/V spectral ratio, although the physical explanation of this peak is still under discussion, since both reverberating SH body waves as well as the ellipticity characteristics of Rayleigh surface waves may account for its existence. However, it has been demonstrated that both hypotheses explain the observations equally well in case of large impedance contrasts and simple stratigraphy (Malischewsky and Scherbaum, 2004).

Ambient vibration array techniques are logistically more demanding, but allow for the direct estimation of wave propagation characteristics, i.e., apparent wave velocity and direction of the seismic wave front. Frequency-wavenumber (f-k) and autocorrelation techniques are used to obtain the apparent phase velocity within narrow frequency bands. The resulting frequency-dependent phase velocity curves are interpreted as dispersion curve branches of surface waves and are inverted for the physical properties of 1-D Earth models parameterized as stack of horizontally homogeneous layers. Since the dispersion curve inversion constitutes a highly non-linear and non-unique problem, it is of utmost importance to obtain an accurate dispersion curve measurement and a well-founded interpretation of observations. Considering the resolution capabilities of array settings with a low number of sensors, adaptive measurement strategies have to be used to capture the full available wavelength range of the surface waves included in the ambient vibration wavefield (Bonnefoy-Claudet et al., 2005). Starting with small inter-station distance and small aperture provides a good estimate of the shallow shear wave velocity which can be used to optimize the array configuration for redeployment with larger apertures and inter-station distances. Thus, the array configuration is iteratively adapted to the next larger target wavelength. A proposed work flow can be found, e.g., in Jongmans et al. (2005). Further, a priori information (e.g., shallow shear wave velocities derived from hammer blow refraction seismic, borehole stratigraphies) may help to reduce the non-uniqueness of the inverse problem.

### **9.10.3 Array geometry for ambient vibration measurements**

The optimal array geometry for ambient vibration measurements has been discussed by e.g., Asten and Henstridge (1984) and Kind (2002). Whereas small aperture arrays designed for monitoring natural or man-made seismic sources are optimized for (usually undispersed) broadband transient signal arrivals from relatively distant sources (see also Section 9.7), arrays used for ambient vibration measurements are supposed to record a mostly random wavefield caused by nearby superficial sources, which is analyzed within narrow frequency bands (Jongmans et al., 2005). The resolution of narrowband array responses is significantly reduced compared to wide-band array responses and aliasing peaks are fully developed due to the lack of superpositioning of beam patterns for different frequencies (Jongmans et al., 2005; see also Fig. 9.24). The resolution can be enhanced by using either a large number of sensors or choosing the array size according to the specific narrow wavelength range of interest, which means re-deployment of several array configurations for different frequency ranges as mentioned in Section 9.10.2. For ambient vibration measurements, Jongmans et al. (2005) recommend a circular array deployment with an odd number of stations (see also Section 9.12) since this configuration is known to have the best possible azimuthal suppression capability for a given number of sensors and allows for analysis using f-k as well as autocorrelation methods.

### **9.10.4 Estimation of phase velocity curves**

The ability to extract phase velocity curves from ambient vibration measurements within specific frequency bands is inherently coupled with the propagation characteristics at the site and the nature of ambient vibration sources on the one hand, and with experimental conditions and data analysis procedures on the other hand (Jongmans et al., 2005). In principle, either Rayleigh or Love wave phase velocity curves can be produced, but often, only Rayleigh-wave

dispersion curves are analyzed (see, e.g., Okada, 2003, for a general discussion about three-component ambient vibration analysis).

Data processing methods can be classified in two basic types: f-k methods and autocorrelation methods. The first class of methods comprises the conventional semblance based frequency-wavenumber method (CVFK) after Kværna and Ringdal (1986; see also Section 9.8), which is implemented using sliding time windows and narrow frequency bands around a center frequency (see, e.g., Dietrich et al., 2001). Capon (1969a) formulated a high-resolution f-k approach, which optimizes the windowing function based on the evaluation of the cross spectral matrix (CSM matrix) such that the wavenumber response approaches a delta-function in the f-k domain. However, the gain in slowness resolution is traded against a lack of time resolution caused by the estimation of the cross spectral matrix ("block averaging") and its inversion. Since the construction of the windowing function involves the signal itself, the response cannot be independently studied from the signal. Only a lower limit of slowness resolution can be derived from the beam pattern (Kind, 2002). Another f-k analysis method is the MUSIC algorithm (Multiple Signal Classification, Schmidt, 1986; Schmidt and Franks, 1986) decomposing the CSM matrix into signal and noise subspaces.

For an overview on the extraction process of dispersion curves from ambient vibration data, see Fig. 9.35. In order to extract the most coherent plane wave arrival, a grid search is performed in the wavenumber plane. For every frequency band of interest and every time window, a slowness map is computed. For each slowness map, the maximum is extracted resulting in the propagation parameters (azimuth and slowness as a function of frequency). These propagation parameters along with the beampower value are analyzed as histograms for their distributional characteristics, and the mean curve and variance are estimated. Such a dispersion curve is computed for each sub-array. Dispersion curves are subsequently combined within the resolution limits of the respective arrays (for a more detailed description, see, e.g., Bonnefoy-Claudet et al., 2005).

Aki (1957) developed a spatial autocorrelation method (SPAC). The spatial autocorrelation function describes the similarity between seismograms recorded by station pairs with similar interstation distance. By filtering with a narrow passband before correlation, the frequency-dependence of the spatial autocorrelation function can be investigated. Assuming a stochastic wavefield that is stationary in time and space, the spatial autocorrelation function depends directly on the phase velocity (Aki, 1957). By azimuthal averaging of the spatial autocorrelation function (averaging for station pairs having equal inter-station distances, but different azimuths), the directionally independent autocorrelation coefficients can be expressed by using Bessel functions. In the same manner as for the f-k method, the analysis is performed with sliding time windows. For each time window, the spatially averaged autocorrelation curve is computed and subsequently, the mean curve and variance are calculated over all time windows. The autocorrelation curve can either be inverted directly for the shear-wave velocity profile or transformed into a dispersion curve first. Since several station pairs with equal inter-station distance are required for azimuthal averaging, the array configuration has to be circular (Aki, 1957) or at least regular (extended spatial autocorrelation (ESPAC), see Ohori et al., 2002). Bettig et al. (2001) modified the SPAC method (MSPAC) for application to less ideal array configurations by grouping the seismic co-array (Haubrich, 1968) into rings of finite thickness introducing a radial integration corresponding to an average over all autocorrelation coefficients within a particular ring in addition to the azimuthal integration.

**Fig. 9.35** How to extract dispersion curves using f-k methods: a) compute slowness map for every frequency band of interest and every time window, pick maximum; b) insert slowness values into frequency-slowness plot, one slowness value is extracted for every frequency band and every time window, and a mean curve including variance is computed; c) a dispersion curve is extracted for every sub-array, these are combined within their respective resolution limits (given by colored lines) to give the final dispersion curve (figures partly produced using geopsy/dinver software; Wathelet et al., 2004; Wathelet, 2008).

### 9.10.5 Inversion of dispersion curves to obtain shear wave velocity profiles

A software package readily available to deal with the determination of dispersion curves from ambient vibration array recordings and their inversion is the *geopsy/dinver* software (Wathelet et al., 2004; Wathelet, 2008; see Fig. 9.36 for an example). The *geopsy* software package implements f-k methods (CVFK and a so-called high resolution f-k algorithm (HRFK)) as well as autocorrelation methods (MSPAC) following the implementation in the CAP software developed within the framework of the SESAME project. Within the *dinver* software, the inversion of dispersion curves is performed using a neighbourhood algorithm (Sambridge 1999a and b) linked to a revised version of the forward computation by Herrmann (1987).

### 9.10.6 Difficulties

So far, only little work has been done on the reliability of the dispersion curve estimate and the dispersion curve inversion (for results of an international blind test see Cornou et al.,

2006). In general, dispersion curves derived from ambient vibration array analysis are reproducible and remain temporally stable although the sources exciting the wavefield may change. This stability is a consequence of the randomness of the source distribution and the attenuation properties of the medium (Bonnefoy-Claudet et al., 2005). However, the main assumptions on which the data inversion is based, namely that the subsurface is one-dimensional, i.e., horizontally stratified, and that ambient vibrations consist mainly of surface waves may not be a reasonable approximation under the given conditions (Jongmans et al., 2005).

One of the main difficulties in the analysis of ambient vibrations results from the lack of knowledge on the nature of the wavefield, e.g., spatio-temporal distribution of sources, source types, source depths, type and energy content of the radiated waves (Jongmans et al., 2005). The f-k techniques are best suited for the analysis of ambient vibrations resulting from a single source or an azimuthally constrained dominant source region, whereas for the MSPAC analysis, a random source distribution is most favorable. Thus, complementary information of both techniques can be used to enhance phase velocity estimates.
